PRINTING AND BOOKBINDING COMPANY
NEW YORK

LIST OF CONTRIBUTORS TO VOLUME IX.

ROBERT ABBE, M.D.....NEW YORK, N. Y.
Attending Surgeon, St. Luke's Hospital; Consulting Surgeon, Hospital for Ruptured and Crippled.

SAMUEL W. ABBOTT, M.D.....BOSTON, MASS.
Secretary of State Board of Health of Massachusetts.

MAJOR GEORGE W. ADAIR, M.D.....FORT ROBINSON, NEB.
Surgeon, United States Army.

CHARLES W. ALLEN, M.D.....NEW YORK, N. Y.

JOHN AULDE, M.D.....PHILADELPHIA, PA.
Editor of the "American Therapist."

FRANK BAKER, M.D., PH.D....WASHINGTON, D. C.
Professor of Anatomy, Georgetown University, Washington, D.C.

CHARLES P. BANCROFT, M.D.....CONCORD, N. H.
Superintendent of the New Hampshire Asylum for the Insane.

WILLIAM BARNES, S.B., M.D.....DECATUR, ILL.

A. D. BLACKADER, M.D.....MONTREAL, CANADA.
Professor of Pharmacology and Therapeutics, and Lecturer on Diseases of Children, McGill University; Physician to the Montreal General Hospital.

ALBERT N. BLODGETT, M.D.....BOSTON, MASS.

MEADE BOLTON, M.D.....BALTIMORE, MD.
Pathological Laboratory, Johns Hopkins Hospital.

JOHN W. BRANNAN, M.D.....NEW YORK, N. Y.
Visiting Physician, Bellevue Hospital.

GEORGE EMERSON BREWER, M.D...NEW YORK, N. Y.
Assistant Demonstrator of Anatomy, College of Physicians and Surgeons.

NORMAN BRIDGE, M.D.....,.LOS ANGELES, CAL.

WILLIAM BROWNING, M.D.....BROOKLYN N. Y.
Lecturer on Normal Neurology at the Long Island College Hospital; Neurologist to the Long Island Dispensary.

JOSEPH D. BRYANT, M.D..... NEW YORK, N. Y.
Visiting Surgeon, Bellevue and St. Vincent's Hospitals.

J. WELLINGTON BYERS, M.D...CHARLOTTE, N. C.

HENRY T. BYFORD, M.D.....,.....CHICAGO, ILL.
Professor of Gynæcology, College of Physicians and Surgeons of Chicago, and of the Post-Graduate Medical School of Chicago; Gynæcologist to the Woman's Hospital, to St. Luke's Hospital, and to the Chicago Hospital.

HENRY DWIGHT CHAPIN, M.D.NEW YORK, N. Y.
Professor of Diseases of Children at the New York Post-Graduate Medical School and Hospital.

T. M. CHEESMAN, M.D.....NEW YORK, N. Y.
Instructor in Bacteriology, College of Physicians and Surgeons, Medical Department of Columbia College.

FREDERIC COGGESHALL, M.D.....BOSTON, MASS.
Physician to the Boston Dispensary, Department of Nervous Diseases; Pathologist to the Carney Hospital.

WILLIAM B. COLEY, M.D .....NEW YORK, N. Y.
Attending Surgeon, New York Cancer Hospital.

JOSEPH COLLINS, M.D.....NEW YORK, N. Y.
Instructor in Nervous Diseases, New York Post-Graduate Medical School and Hospital.

WILLIAM JUDKINS CONKLIN, M.D...DAYTON, O.

EDWARD COWLES, M.D., LL.D.....SOMERVILLE, MASS.
Medical Superintendent of the McLean Hospital, Somerville, Mass.; formerly Superintendent of the Boston City Hospital; Clinical Instructor in Mental Diseases, Harvard Medical School.

GEORGE A. CRAIGIN, M.D.....BOSTON, MASS.
Physician to Staniford Street Dispensary, Department of Women; Physician to House of the Good Samaritan.

ANDREW F. CURRIER, M.D.....NEW YORK, N. Y.
Gynæcologist to Bellevue Hospital, Out-Patient Department.

B. FARQUHAR CURTIS, M.D....NEW YORK, N. Y.
Attending Surgeon, St. Luke's Hospital.

THOMAS DARLINGTON, JR., M.D.....NEW YORK, N. Y.
Visiting Physician to the New York Foundling Hospital; formerly Physician to the Copper Queen Consolidated Mining Company.

N. S. DAVIS, M.D., LL.D.....CHICAGO, ILL.
Emeritus Professor of Principles and Practice of Medicine and of Clinical Medicine, Northwestern University Medical School; Professor of Medical Jurisprudence, Northwestern University Law School.

ROBERT H. M. DAWBARN, M.D.....NEW YORK, N. Y.
Professor of Operative Surgery and Surgical Anatomy in the New York Polyclinic.

EDWARD B. DENCH, M.D.....NEW YORK, N. Y.
Aural Surgeon, New York Eye and Ear Infirmary.

L. M. DENNIS, Ph.B., B.S.....ITHACA, N. Y.
Assistant Professor of Analytical Chemistry, Cornell University.

HASKET DERBY, M.D.....BOSTON, MASS.
Ophthalmic Surgeon, Massachusetts Charitable Eye and Ear Infirmary.

F. X. DERCUM, M.D.....PHILADELPHIA, PA.
Clinical Professor of Diseases of the Nervous System, Jefferson Medical College; Neurologist to the Philadelphia Hospital.

CHARLES N. DOWD, M.D.....NEW YORK, N. Y.
Asssistant Surgeon to the New York Cancer Hospital.

THEODORE DUNHAM, M.D.....NEW YORK, N. Y.

ROBERT G. ECCLES, M.D.....BROOKLYN, N. Y.
Chairman of the Sub-Committee on Active Principles of the United States Pharmacopœia; Government Medical Chemist for the Department of the Interior.

JOHN SLADE ELY, M.D.....NEW YORK, N. Y.
Professor of Pathology, Women's Medical College of the New York Infirmary; Assistant in Pathology, College of Physicians and Surgeons; Pathologist to Bellevue Hospital; Assistant Physician, Roosevelt Hospital, Out-Patient Department.

HAROLD C. ERNST, M.D.....BOSTON, MASS.
Assistant Professor of Bacteriology in Harvard University; Physician to Out-Patients at the Massachusetts General Hospital.

PIERRE A. FISH, B.S.....ITHACA, N. Y.
Instructor in Physiology, Vertebrate Zoölogy, and Neurology, Cornell University.

WILLIAM H. FORD, M.D.....PHILADELPHIA, PA.
President of the Board of Health, Philadelphia; Member of the American Public Health Association.

GEORGE R. FOWLER, M.D.....BROOKLYN, N. Y.
Attending Surgeon, St. Mary's and Methodist Episcopal Hospitals.

JAMES M. FRENCH, M.D.....CINCINNATI, OHIO.
Lecturer on Morbid Anatomy and Demonstrator of Pathology, Medical College of Ohio; Physician to St. Mary's Hospital, Cincinnati.

J. McF. GASTON, M.D.....ATLANTA, GA.

H. GRADLE, M.D.....CHICAGO, ILL.
Eye and Ear Surgeon to the Michael Reese Hospital.

DOUGLAS GRAHAM, M.D.....BOSTON, MASS.

JAMES E. GRAHAM, M.D.....TORONTO, CANADA.
Lecturer on Diseases of the Integumentary System, Toronto School of Medicine.

LIEUT.-COL. CHARLES R. GREENLEAF, M.D....
WASHINGTON, D. C.
Deputy Surgeon-General, United States Army.

JOHN B. HAMILTON, M.D.....CHICAGO, ILL.
Late Surgeon-General, United States Marine Hospital Service.

HORACE T. HANKS, M.D.....NEW YORK, N. Y.
Attending Surgeon, Woman's Hospital.

A. H. HARRIMAN, M.D.....LACONIA, N. H.

ROBERT P. HARRIS, M.D.....PHILADELPHIA, PA.

GEORGE HAVEN, M.D.....BOSTON, MASS.
Gynæcologist to Out-Patients, Boston City Hospital; Gynæcologist to the Boston Dispensary; Physician to Out-Patients, Boston Lying-in Hospital.

CLARENCE L. HERRICK, M.D.....GRANVILLE, O.
Professor of Biology, Denison University.

S. S. HERRICK, M.D.....SAN FRANCISCO, CAL.

WILLIAM B. HILLS, M.D.....BOSTON, MASS.
Associate Professor of Chemistry, Harvard Medical School.

WILLIAM H. HINGSTON, M.D., LL.D.....MONTREAL, CANADA.
Professor of Clinical Surgery, Montreal School of Medicine (Laval University); Surgeon to the Hôtel-Dieu.

RICHARD HODGSON, M.A., LL.D...BOSTON, MASS.
Secretary of the American Branch of the Society for Psychical Research.

WILLIAM H. HOWELL, M.D.....BALTIMORE, MD.
Professor of Physiology, Johns Hopkins University.

JOHN H. HUDDLESTON, M.D....NEW YORK, N. Y.
Attending Physician, Gouverneur Dispensary.

JAMES NEVINS HYDE, M.D .....CHICAGO, ILL.
Professor of Skin and Venereal Diseases, Rush Medical College.

FREDERICK W. JOHNSON, M.D.....BOSTON, MASS.
Surgeon to the Gynæcological Department of St. Elizabeth's Hospital, and of Carney Hospital.

WILLIAM W. JOHNSTON, M.D.....WASHINGTON, D. C.
Professor of Theory and Practice of Medicine, Medical Department of Columbian University, Washington; Consulting Physician to Garfield, Children's, and Emergency Hospitals, Washington.

WYATT JOHNSTON, M.D.....MONTREAL, CANADA.
Demonstrator of Bacteriology, McGill University.

WILLIAM W. KEEN, M.D., LL.D....PHILADELPHIA, PA.
Professor of Principles of Surgery and of Clinical Surgery, Jefferson Medical College; Surgeon to the Jefferson Medical College Hospital, and the Philadelphia Orthopædic Hospital and Infirmary for Nervous Diseases.

CHARLES B. KELSEY, M.D..... NEW YORK, N. Y.

RUFUS A. KINGMAN, M.D..... BOSTON, MASS.
Instructor in Gynæcology in the Boston Polyclinic; Gynæcologist to the Boston Dispensary for Diseases of Women, to St. Elizabeth's Hospital, and to Carney Hospital.

CARL KOLLER, M.D.....NEW YORK, N. Y.
Lecturer on Diseases of the Eye, New York Polyclinic; Surgeon to the Eye Department, Mount Sinai Dispensary; Member of the *Heidelberger Ophthalmologische Gesellschaft*.

S. P. KRAMER, M.D.....CINCINNATI, O.
Professor of Pathology and Bacteriology, and Lecturer on Clinical Surgery, Cincinnati College of Medicine and Surgery.

CHARLES McK. LEOSER, ESQ....NEW YORK, N. Y.

FRANKLIN P. MALL, M.D.....BALTIMORE, MD.
Professor of Anatomy, Johns Hopkins University.

ANDREW J. McCOSH, M.D.....NEW YORK, N. Y.
Attending Surgeon, Presbyterian Hospital.

MIDDLETON MICHEL, M.D.....CHARLESTON, S. C.
Professor of Medical Jurisprudence and Physiology, Medical College of the State of South Carolina; Attending Surgeon, City Hospital, Charleston.

WILLIAM S. MILLER, M.D.....MADISON, WIS.
Instructor in Vertebrate Anatomy, University of Wisconsin.

WESLEY MILLS, M.D.....MONTREAL, CANADA.
Professor of Physiology, McGill University.

J. L. MINOR, M.D.....MEMPHIS, TENN.

JOHN H. MUSSER, M.D.....PHILADELPHIA, PA.
Assistant Professor of Clinical Medicine, University of Pennsylvania; Physician to Philadelphia and Presbyterian Hospitals.

SAMUEL NICKLES, M.D.....CINCINNATI, O.
Professor of Materia Medica and Therapeutics and Clinical Medicine, Medical College of Ohio.

JOSEPH O'DWYER, M.D.....NEW YORK, N. Y.
Visiting Physician, New York Foundling Hospital.

OSCAR OLDBERG, Phar.D.....CHICAGO, ILL.
Professor of Pharmacy, School of Pharmacy, Northwestern University, Chicago.

HENRY F. OSBORN, Sc.D.....NEW YORK, N. Y.
Da Costa Professor of Biology, Columbia College.

OLIVER T. OSBORNE, M.D.... NEW HAVEN, CONN.
Assistant Professor of Materia Medica and Therapeutics, Yale University.

AUSTIN PETERS, B.S., D.V.S., and M.R.C.V.S., BOSTON, MASS.

FREDERICK PETERSON, M.D.....NEW YORK, N. Y.
Chief of Clinic, Nervous Department, Vanderbilt Clinic, College of Physicians and Surgeons.

GEORGE A. PIERSOL, M.D. ....PHILADELPHIA, PA.
Professor of Anatomy in the University of Pennsylvania.

CAPT. JAMES E. PILCHER, M.D., FORT RINGGOLD, RIO GRANDE CITY, TEX.
Assistant Surgeon, United States Army.

F. PEYRE PORCHER, M.D., LL.D., CHARLESTON, S. C.
Professor of Materia Medica and Therapeutics, Medical College of the State of South Carolina; Attending Physician, City Hospital, Charleston.

J. PICKERING PUTNAM, Esq.....Boston, Mass.

MARY PUTNAM-JACOBI, M.D., New York, N. Y.
Consulting Physician, New York Infirmary for Women and Children,

LEOPOLD PUTZEL, M.D.....New York, N. Y.
Visiting Neurologist, Randall's Island Hospitals.

B. ALEXANDER RANDALL, M.D., Philadelphia, Pa.
Clinical Professor of Ear Diseases, University of Pennsylvania; Professor of Otology, Philadelphia Polyclinic; Ophthalmic and Aural Surgeon, Children's Hospital.

J. C. REEVE, M.D.....Dayton, O.

EDWARD T. REICHERT, M.D., Philadelphia, Pa.
Professor of Physiology, University of Pennsylvania.

CHARLES RICE, Ph.D.....New York, N. Y.
Chemist of Department of Public Charities and Correction, New York City; Chairman of Committee of Revision and Publication of the Pharmacopœia of the United States of America.

CLARENCE C. RICE, M.D.....New York, N.Y.
Professor of Diseases of the Nose and Throat, Post-Graduate Medical School and Hospital.

JOHN RIDLON, M.D.....Chicago, Ill.
Professor of Orthopedic Surgery in the Northwestern University Medical School, and the Chicago Post-Graduate Medical School; Orthopedic Surgeon to St. Luke's Free Hospital of Chicago.

A. D. ROCKWELL, M.D.....New York, N. Y.

THOMAS H. RUSSELL, M.D....New Haven, Conn.
Professor of Clinical Surgery and Surgical Anatomy, Yale University.

WILLIAM T. SEDGWICK, Ph.D.....Boston, Mass.
Professor of Biology, Massachusetts Institute of Technology; and Chief Biologist to the State Board of Health of Massachusetts.

GEORGE B. SHATTUCK, M.D.....Boston, Mass.
Visiting Physician, Boston City Hospital.

BEAUMONT SMALL, M.D.....Ottawa, Canada.
Examiner in Materia Medica and Pharmacy, College of Physicians and Surgeons of Ontario; Attending Physician, General Protestant Hospital, Ottawa.

COLONEL JOSEPH R. SMITH, M.D., San Francisco, Cal.
Assistant Surgeon-General, United States Army.

HENRY R. STEDMAN, M.D.....Boston, Mass,
Superintendent of "Woodbourne" (Hospital for Nervous and Mental Disease).

THOMAS LATHROP STEDMAN, M.D., New York, N. Y.

LOUIS McLANE TIFFANY, M.D., Baltimore, Md.
Professor of Surgery, University of Maryland.

CHARLES W. TOWNSEND, M.D.... Boston, Mass.
Physician to Out-Patients at the Massachusetts General, Children's, and Lying-in Hospitals.

ROGER S. TRACY, M.D.....New York, N. Y.
Deputy Register of Vital Statistics, Health Department, City of New York.

F. TUCKERMAN, M.D.....Berlin, Germany.

A. VANDER VEER, M.D..... Albany, N. Y.
Professor of Didaetic, Clinical, and Abdominal Surgery, Albany Medical College.

ELY VAN DE WARKER, M.D.....Syracuse, N. Y.
Surgeon to the Central New York Hospital for Women; Surgeon to the Syracuse Woman's and Children's Hospital; Consulting Surgeon to St. Ann's Maternity Hospital.

LEONARD WEBER, M.D... ...New York, N. Y.
Consulting Physician to St. Mark's and St. Joseph's Hospitals.

EDMUND C. WENDT, M.D.....New York, N. Y.

MOSES C. WHITE, M.D.....New Haven, Conn.
Professor of Pathology, Yale University.

JAMES T. WHITTAKER, M.D., LL.D.....Cincinnati, O.
Professor of Theory and Practice of Medicine, Medical College of Ohio; Lecturer on Clinical Medicine, Good Samaritan Hospital.

BURT G. WILDER, M.D.....Ithaca, N. Y.
Professor of Comparative Anatomy and Zoölogy, Cornell University.

CHARLES F. WITHINGTON, M.D... Boston, Mass.

ALFRED C. WOOD, M.D..... Philadelphia, Pa.
Instructor in Clinical Surgery, University of Pennsylvania; Assistant Surgeon, University and Gynecean Hospitals, Philadelphia.

MAJOR ALFRED A. WOODHULL, M.D.....Hot Springs, Ark.
Surgeon, United States Army.

CAPTAIN CHARLES E. WOODRUFF, M.D...Fort Assinniboine, Mon.
Assistant Surgeon, United States Army.

PHILIP ZENNER, M.D.....Cincinnati, O.
Clinical Lecturer on Diseases of the Nervous System, Medical College of Ohio.

PREFACE.

THE present volume is the outcome of a decision to bring THE REFERENCE HANDBOOK OF THE MEDICAL SCIENCES fully up to date. It was at first contemplated to revise the volumes of the work and issue a new edition of the whole; but as this would practically make obsolete the great number of sets of the HANDBOOK now in the libraries of physicians all over the world, it was considered preferable to publish a supplementary volume, which could be added to those already issued, completing, rather than destroying, the original edition, and at the same time enabling present possessors of the work to obtain the new matter at a comparatively small cost. Although the original work was published at short intervals during the period from 1885 to 1889, and consequently is not very old in point of years, nevertheless in some of its departments—especially those of Pathology, Materia Medica, and Therapeutics—the changes that have taken place in even this brief period of time are so great as to be almost startling in their magnitude. Much of this newly acquired knowledge still lies scattered throughout periodical medical literature, and has not yet been incorporated into the text-books that are used by a large proportion of the profession. The present, therefore, seemed a good time in which to gather together into a single supplementary volume all this scattered knowledge.

Soon after the work was inaugurated, it was found—as we then believed—that all of the available space would not be required for the adequate presentation of this recently acquired knowledge. Accordingly, provision was made for the introduction of a number of articles on different topics which had not been discussed at all in the original work. Many of these, it was thought, would add materially to the usefulness of the book as a work of reference.

In the progress of the undertaking the Editor has received valuable assistance from the following individuals, to all of whom he would now offer his grateful acknowledgments: Dr. John Green, of St. Louis, Mo.; Dr. Thomas Lathrop Stedman, of New York; Professor Charles Sedgwick Minot and Dr. William N. Bullard, of Boston, Mass.; Dr. Beaumont Small, of Ottawa, Canada; Professor Burt G. Wilder and Professor Simon H. Gage, of Ithaca, N. Y.; and Lieutenant-Colonel Charles R. Greenleaf, Major Alfred A. Woodhull, and Major John Van R. Hoff, of the Medical Staff of the United States Army.

He also takes pleasure in acknowledging the generosity manifested by the publishers in the present undertaking; for when it became evident that the volume could not be kept within the limits (number of pages) set by them beforehand, and so announced in their published circulars, unless some articles should be omitted altogether, and others very much shortened, they authorized him to publish all this material in its entirety, notwithstanding the great increase in cost to which they would thereby be subjected, without any addition in the pecuniary returns to them. In consequence of this decision the volume, as may be noticed, far exceeds any of its predecessors in the number of pages which it contains.

ALBERT H. BUCK.

SUPPLEMENT TO THE

REFERENCE HANDBOOK

OF THE

MEDICAL SCIENCES.

ABANO. An Italian watering-place, known to the Romans as Aquæ Aponi, or Aquæ Patavinæ.

LOCATION.—In the province of Venetia, six miles from Padua.

ACCESS.—From Paris, *via* the Paris, Lyons & Mediterranean Railroad; then through the Mont Cenis, Turin, Milan, Padua; or by steamer from New York to Genoa, and thence to Padua.

INDICATIONS.—These celebrated hot (200° F.) sulphur springs are much used in rheumatism, gout, scrofula, and all cutaneous and syphilitic affections. There are ten bathing establishments, with modern appliances. The waters contain bromine and iodine, but a reliable analysis is not at hand. Peat baths are also employed.

ACCOMMODATION.—Hotels and lodging-houses are not of the best. The village is interesting, but not clean.

Edmund C. Wendt.

ABBAZIA. One of the newer and most popular health-resorts of Austria.

LOCATION.—Abbazia is situated on a pretty bay of the Adriatic, in Istria, district of Finme, and about one hour's drive from the city of that name. It is fairly well sheltered from the north, east, and west winds. The Monte Maggiore acts as a protecting barrier. It is known as a resort on the "Austrian Riviera."

ACCESS.—By the Austrian "Südbahn," one hour from the station Matuglie.

INDICATIONS.—Abbazia has become decidedly popular recently as a winter station for neurasthenic people; also for subacute and chronic catarrhal affections of the respiratory organs. On account of its attractive location it is also used by the natives as a summer resort. Sea-bathing, promenades in pretty parks, establishments for inhalation, massage, mechano-therapy, etc., are among its resources.

Dr. Glax maintains the superiority of the winter climate of Abbazia over many other similar stations (*Aerztliche Mittheilungen aus Abbazia*, Wien, 1892). He gives elaborate tables of meteorological observations in substantiation of his views. But the impartial observer will only perceive that the climate of this resort somewhat resembles that of the Riviera generally, but is rather more moist than that district. The sanitary arrangements of the place are said to be satisfactory, and of its natural attractiveness there is no doubt. Nevertheless, Dr. Glax must be regarded as a local enthusiast.

ACCOMMODATION.—There is a large hotel, the Grand Hotel Abbazia, several minor ones, and a *Kuranstalt* called "Quisisana." Five or six physicians are in attendance. The winter season lasts from October to May. Splendid promenade along the shore.

Edmund C. Wendt.

ACETANILIDE (Phenylacetamide, Antifebrin). Of the host of new remedies that have been received during the past few years, this is one that has received general approbation and has sustained the reputation with which it was introduced. In Great Britain it has received official recognition by being placed in the Pharmacopœia of 1890. Since its introduction in 1886, by Drs. Kahn and Hepp, it has been extensively employed, without detracting from their estimate of its virtues. Further study has established its antipyretic and analgesic properties, and were it not that in phenazone and phenacetine we have drugs with a similar action it would be prized as of inestimable value. The tendency it has to cause profuse sweating and a condition of cyanosis has unfortunately engendered in many a sense of dread which has restricted its use. This toxicity is greatly over-estimated and should not be feared if the dose and mode of administering are attended to. It is rather a danger-signal far in advance of any serious consequences.

Kahn and Hepp in their original papers stated that one-fourth of a gramme (3.85 grains) was a sufficient dose, and subsequent writers have insisted on the efficacy of even smaller quantities.

Instead of the seven or ten grains so frequently given, the consensus of opinion now points to three or four grains as a more proper initial dose in every case where its use is begun, to be increased as the individual susceptibility is learned. There are also many points to be considered in its administration which influence its action. As the effect of the dose is continued for two or three hours the dose should not be repeated until that interval has elapsed. Where the use of the drug is persisted in for some time a day of freedom from its use should occasionally be allowed to intervene, as it undoubtedly possesses a sort of cumulative action. Many instances are reported where severe toxic symptoms have followed the same dose that had been given for some days with only beneficial effects. When the patient is anæmic, and in the debilitated and aged, the toxic symptoms more readily supervene, and in women, during the few days previous to menstruation, the condition of the blood is supposed to favor the decomposition of the drug and increase its action. The time of the dose, in relation to the natural rise or decline of temperature, is of importance; when given with the increase of fever its action is slower and within control, but if its effect coincides with the decline the fall will be rapid and probably in excess of what is expected.

Although the toxic symptoms are alarming it is a question as to how far they are dangerous. The cyanosis and sense of depression is not of long duration and is rapidly overcome. Fatal cases are rare and very large quantities of the drug have been taken without causing death. A case is reported in which teaspoonful doses were taken at short intervals until one ounce was disposed of, and in another instance seven and a half drachms were taken with suicidal intent. In both cases recovery followed.

Acetanilide possesses many advantages over other antipyretics. Its action is rapid and certain; the amount required is small and easily taken by the patient; it has no irritating effect on the digestive organs, but rather promotes digestion and improves the well-being of the body; and, what is of greater importance, it is devoid of any depressive action on the heart or circulation.

The toxic condition arises from an altered state of the blood and disordered function of the medulla and spinal

cord. The early symptoms are profuse perspiration and a bluing of the finger-nails and lips, accompanied by a sense of oppression; then follow vertigo and giddiness, singing in the ears, dilated pupils, cold extremities, subnormal temperature, slow and shallow breathing, feeble pulse, nervous twitchings, and convulsions.

How the drug produces its action is as yet undetermined. There is a lessening of the oxidizing property of the blood and the production of methæmoglobin, the arterial blood becomes of a dirty brown color, the serum becomes colored and hæmoglobinuria supervenes. In extreme cases and where the drug is administered for a prolonged period, it produces a state of anæmia. The disturbances in the medulla are considered to be secondary to the condition of the blood and not due to any direct action of the drug on the nerve-centres.

To counteract the poisoning, stimulating treatment is indicated. Warmth to the extremities and surface; alcohol, ether, and camphor by the mouth or hypodermically; belladonna is particularly recommended for its stimulant action on the centres, four drops of the tincture every half hour for four doses, afterward at longer intervals, having proved of service. Strychnine is also useful. The inhalation of oxygen is indicated. In extreme prostration the transfusion of saline solution has been adopted with benefit.

Acetanilide in fever is used solely as an antipyretic, and as such it has been classed as one of the best we possess. It is utilized in typhoid fever, pneumonia, phthisis, erysipelas, acute rheumatism, and in all conditions in which hyperpyrexia is present. It was thought by some to have specific properties in many of these disorders, but such views are no longer tenable; the duration of the disease is not affected, complications are not prevented, nor does it guard the patient against relapses. It reduces the high temperature and relieves the discomfort and distress that are present, and its sedative action on the nervous system adds to its calming and refreshing effect. Its continuous administration is not advised, but only its use when the temperature is such as to require interference.

In phthisis it proves particularly soothing, and by judiciously controlling the pyrexia night-sweats are lessened and prevented. In the hyperpyrexia of pneumonia it is used with advantage, but in this condition, as well as in advanced phthisis, where the respiratory tissue is reduced, it must be given with caution.

In acute rheumatism it relieves the painful and swollen joints and reduces the temperature. When the pains are severe it requires larger doses than in other febrile affections. Its action is generally thought not to be so efficacious as that of antipyrin or salicylate of soda, but it has not their disturbing influence on the digestive organs, and may be given where these drugs are not well borne.

Its analgesic properties have proved almost as decided as its power of reducing pyrexia. It is particularly useful in all pains due to irritation of the sensory nerves or pains of a reflex character, such as pains of locomotor ataxia, neuralgia, sciatica, lumbago, pains after operations, ovarian and menstrual irritation; also in migraine, nervous headaches, the headaches of growing children, and all paroxysmal pains it has proved equally successful.

It has been recommended and tried in epilepsy and chorea but without much advantage.

In the diseases of infancy it has proved of decided usefulness. Its effects are of longer duration and the toxic symptoms are not so liable to follow its use. In scarlet fever, measles, pneumonia, etc., its action has been most gratifying, reducing fever and restlessness and inducing a quiet and refreshing sleep. In whooping-cough it is also used with success; its action promotes expectoration and reduces the frequency and duration of the paroxysms.

Beaumont Small.

ACIREALE. A much-frequented climatic health-resort with thermal waters in Sicily, Italy.

Location.—Acireale is situated in the province of Catania, on the southern slope of Mount Etna. It has an elevation of 560 feet above sea-level, and has an old-established reputation, the springs having been known to the ancients as Aqua Santa Venere.

Access.—It is two hours' ride from Messina, on the Messina-Catania Railroad.

Indications.—The native Italians regard Acireale as an all the year round resort, but foreigners go there only in the winter season. The waters are sulpho-saline, and also contain iodides. The springs have a temperature of 70° F. They are used with advantage in rheumatism, gout, scrofula, and metallic poisoning; also in paralysis and neuralgia. The climate is said to benefit phthisis, emphysema, chronic respiratory troubles, anæmia, chlorosis, and neurasthenia.

The winter climate of Acireale is dry and mild. The death-rate is stated to be only nineteen per thousand. Mean winter temperature, 55° F. The variations are never more than ten degrees. The number of rainy days in the year range between thirty and fifty, but do not exceed the latter. Snow and fogs are unknown. Windy days are less in number than on the Riviera, and there is a complete absence of dust. The prevailing winds are the S.E., S.W., S.S.E., and E.S.E. The air is rich in ozone, owing to the vicinity of the sea. The luxuriance of the vegetation is almost tropical.

Accommodation.—The principal hotel is the *Grand Hotel des Bains*, facing due south. The town has 30,000 inhabitants. There are several medical establishments.

Edmund C. Wendt.

ACROMEGALY, or Akromegaly (*ακρον*, extremity; *μεγας*, great). Synonyms: Acromégalie; akromegalie; acromegalia; pachyacrie; Marie's disease.

Definition.—Acromegaly is a chronic disease, characterized by an abnormal increase in the size of the extremities of the body, viz., hands, feet, and generally head, due to an hypertrophy of the bones and soft parts of these regions.

History.—The first to recognize this disease as a separate entity was P. Marie, who wrote upon this subject in 1886. This first article of Marie's describes two cases which he had discovered while first assistant to Professor Charcot. He named this disease "Acromégalie" because he found all the extremities of the body enlarged, viz., hands, feet, and cephalic extremity, while von Recklinghausen suggests the name of "pachyaerie." Since the publication of Marie's first paper in 1886, a number of cases, reported in literature under various titles, have been discovered, which in all probability were cases of acromegaly. A few of the titles under which these cases were reported, all of which have unquestionably not yet been discovered, are "Exophthalmic Goître," "Myxœdema," "Hypertrophy of the Tongue," and, more frequently than all the rest, "Gigantism," or giant growth.

On the other hand, since 1886, a number of cases have been reported as acromegaly, which I do not believe to be cases of that disease. Thus far, somethiug more than one hundred cases have been published, some few of which, as just stated, are probably not acromegaly. The first cases discovered and reported as acromegaly (in 1885 Wadsworth reported a case as myxœdema, which was undoubtedly acromegaly) in America were those of Drs. O'Connor and Adler, both of which were published in 1888. In 1890, Marie published an article on a second new disease, which was at first confounded with acromegaly, but which clinically and pathologically is a distinct and entirely different disease ("De l' ostéoarthropathie hypertrophiante pneumique," *Revue de méd.*, 1890).

Most of the literature on acromegaly will be found at the end of this article, but the disease can be readily studied, as a whole, in the following publications: "De l'acromégalie, Maladie de P. Marie," Souza-Leite, Paris, 1890, gives a complete description, in detail, of all of the cases up to that date, thirty-eight in number. A translation of Souza-Leite's article in the New Sydenham Society, London, 1891, contains the above thirty-eight cases, and adds abstracts of ten more. In our own country,

Dr. Joseph Collins, of New York, in a most carefully prepared article, has brought the subject of acromegaly up to 1893, giving abstracts of all the cases reported since the publication of the above Sydenham Society report (*The Journal of Nervous and Mental Diseases*, December, 1892, and January, 1893).

Clinical History.—In acromegaly all of the projecting portions of the body are generally enlarged, hands, feet, chin, lips, nose, tongue, ears, and often the genitalia. Of these parts the bones, cartilages, and soft tissues are all hypertrophied. There is more or less progressive increase in weight, and generally increased appetite and increased thirst. Menstruation almost invariably ceases in the female, and the sexual appetite is generally diminished in the male. There is generally constipation; there may or may not be dyspepsia or polyuria.

Fig. 1.—Author's Case of Acromegaly. General View of Body.

The lower jaw is almost invariably enlarged, and generally to such an extent that prognathism is present. The superior maxillary bones may or may not be enlarged. The malar bones are generally enlarged, rendering the cheek-bones prominent. The supra-orbital ridges are generally projecting, and the forehead retreating.

The cartilages of the nose are enlarged, as are generally the cartilages of the ears and eyelids.

The soft parts of the nose and ears are also generally enlarged, and the nose is often massive. The cranial bones are rarely affected. The lower lip is more frequently enlarged than the upper, and always in excess of it. The face is oval, the cheeks flattened, the forehead retreating and low, the hair of the head strong and thick, and exophthalmos may be present.

The bones of the thorax are always enlarged, notably the extremities of the clavicles, the costal cartilages, especially at their junction with the ribs and the sternum, more especially at the xiphoid appendix. The ribs are generally widened, the scapulæ may or may not be enlarged, and sooner or later the vertebræ and the intervertebral cartilages become affected, the latter thickening and ossifying, causing kyphosis and other deformities of the spinal column. On account of the kyphosis and the shortening of the neck, the long projecting chin often almost rests upon the sternum.

The bones of the arm are generally not enlarged, except the lower part of the radius and ulna, thus causing an enlarged wrist. The bones of the hands, the metacarpal bones and the phalanges especially, are all widened and thickened. The soft parts of the hands are especially hypertrophied, giving the immense and often enormous acromegalic hands.

The pelvic bones are generally enlarged, this being particularly noticeable at the pubis and the crests of the ilia.

The thigh-bones are generally not affected except at the condyles, which are enlarged, and together with the almost constantly enlarged patellæ produce enlarged knee-joints. The tibiæ and fibulæ may or may not be enlarged, though frequently there is some hypertrophy of the extremities of these bones. The ankle-joints are generally enlarged, and the feet-bones and soft parts are affected similarly to the hands, and, like the latter, are enormous.

The heart, lungs, spleen, and liver are normal, although the heart may be slightly hypertrophied. The kidneys are generally normal, although there is often polyuria, but diabetes and albuminuria have sometimes been present.

Pain in the head is the most frequent subjective symptom, often severe and even terrific. There may be, and frequently are, joint-pains, or pains referred to various parts of the body, more or less persistent, but neuralgic in character. Frequently there is tingling of the hands, feet, or ears, often with numbness of the fingers, but with no great loss of sensibility.

There may be muscular hypertrophy, local or general, but later there is atrophy of the muscles.

Taste and smell are rarely affected, hearing is occasionally disturbed, sight is frequently impaired. The voice is loud and deep. The reflexes are generally normal, at least not markedly impaired, and electrical reactions are normal.

The intellectual faculties may or may not be impaired, but the memory is generally poor. Somnolency is sometimes present.

The superficial veins of the body are often enlarged, giving rise to hemorrhoids and varicose veins of the legs.

The skin may be dry and harsh, and is generally greatly thickened on the affected parts. There is often increased perspiration, local or general. The subcutaneous cellular tissue may be hypertrophied or atrophied. There is frequently an increased growth of hair on the body, especially on the arms and legs. The skin is often of a yellow color, especially marked on the face. Frequently molluscous growths appear on the face, neck, or body. Such are the notable symptoms of this interesting and peculiar disease. We will now enter into a more explicit description of the several symptoms.

General Condition.—The acromegalic patient comes to the physician complaining of headache, disturbances of vision, severe joint-pains or ringing of the ears (one case, at least, Osborne); or the case is discovered while the patient is under treatment for an entirely different dis-

ease. The head appears too large for the body, and more careful inspection shows the face to be entirely too large for the rest of the head. The hands and feet are enormous, and out of all proportion to the arms and legs, and, if the case is at all advanced, humpback or kyphosis is present.

The family history and the previous history of the patient himself have, up to the present time, been of no interest, so far as showing exciting or predisposing causes of this disease. There is never increased temperature unless due to an intercurrent affection. The pulse has been almost invariably normal, although it was stated to have increased in rapidity in one of the forty-six cases whose histories I have carefully examined (Godlee's case). There is rarely dyspnœa, and if present, only on exertion. The appetite is generally increased, and may be ravenous, although it is often stated to have been only normal. Thirst may or may not be increased. Constipation is frequently present. Polyuria and dyspepsia may be.

Early History.—In women the cessation of the menstruation is generally the first symptom of the disease. In two cases there was a history, in the early stages, of profuse and recurring epistaxis (Osborne's and Barclay-Symmer's cases). From the patient or his family proof of the continuous growth of the head, hands, feet, and body can generally be elicited, and commonly an approximate date for the beginning of the disease can be estimated.

The increase in size of the hats, shirts, gloves, or shoes can always be ascertained, and are positive evidences of growth.

In women the increase in the size of the fingers, as shown by the inability to longer wear the wedding-ring, which in many cases has been sawed off, is a positive evidence of growth frequently mentioned in the histories of the cases; also in many instances earlier photographs of the patient can be obtained and compared with the present condition. These signs and facts show a positive and continuous growth, and careful examination of the parts affected shows that this growth is largely of the bones.

I could find no definite data as to an increase of height, but it probably does invariably somewhat increase until the period when kyphosis develops, at which time some loss of height may take place, even to six inches in Paget's case. The weight always, at least for a time, increases.

Now, to examine the conditions more in detail we will begin with the head.

Head.—We find the forehead low and retreating, due to the growth forward of the superciliary ridges, which, with the elongation and forward projection of the lower jaw, gives the oval or elliptical face so characteristic of this disease. The hair is thick and strong, and the eyebrows are often heavy. (In Boltz's case the hair was gray.) We next notice that the face is entirely too large, that it is out of all proportion to the cranium proper. The skin of the face is thickened, and of a yellowish brown color, most marked on the eyelids, with, perhaps, here and there a molluscous growth.

The skin of the forehead is often redundant, and thrown into many transverse wrinkles or folds. The cheeks are generally flattened, and often appear sunken, largely due to the prominence and projection of the malar bones. The circumferences of the orbits are prominent, and the eyelids are large, due to the thickening and widening of the tarsal cartilages, with more or less hypertrophy of the skin, especially of the lower lid, where it may fall in folds, with occasionally the appearance of œdema. (In Holsti's case the eyelids were œdematous.) The eyeballs are large and generally more or less prominent, even to the condition of exophthalmos.

The nose, even for the size of the face, is too large, often immense, due to the thickening and enlarging of the nasal cartilages and to the great hypertrophy of the soft parts. It is wide, thick, and may be pugged.

The superior maxillary bones may or may not be enlarged, but are frequently lengthened from above downward; nevertheless, they are never enlarged to the same extent as is the lower jaw.

The upper lip is generally thick and projecting, but never attains the size of the lower lip.

The lower lip is almost invariably large, thick, everted and projecting, and is one of the characteristic features.

The enlargement of the lower jaw is one of the landmarks of this disease, although acromegaly can unquestionably occur without the enlargement of this bone. The angle of junction between the rami and the body becomes obtuse, and, while the rami may grow to considerable extent, the chief growth is in the body. The body of this bone widens and thickens all over, but especially on its alveolar border and at the symphysis, where the mental process becomes very prominent. The rami, however, may be so enlarged and widened as to force outward the lower part of the external ear (Dulles' case). The teeth rarely partake of this growth (in the congenital case described by Cènas the teeth were all enlarged); hence the growth of the alveolar process soon tends to separate the teeth from each other by continually increasing intervals. The teeth may fall out spontaneously (Mosler's case, aged forty-one years).

Sooner or later prognathism generally occurs, due not only to the growth of the body of the lower jaw, but also to the widening of the angle and the changes in the glenoid fossa (see description under Pathological Anatomy). This prognathism is of all degrees, and reached in Gause's case fifteen millimetres.

The external ear is generally increased in size, sometimes even appearing immense.

The cartilages and the soft parts both take part in the growth, and the former may become in places as hard as bone. (The cartilage of the helix of the left ear in the writer's case has apparently developed into bone, while the helix of the right ear is very thick and hard.)

The cartilages which form the outer portion of the external auditory canal, as well as the bony walls of the canal, may take part in this disease, as in the writer's case, where the canals are lengthened by the growth of the cartilages, and the bony canals are narrowed by the growth of exostoses from the superior walls.

The bones of the cranium are generally not enlarged, but the ridges and eminences may be abnormally prominent, especially the occipital protuberance (Adler's, Cènas's, and Campbell's cases). In Massalongo's case there were spiky, osseous protuberances along the sutures of the skull, especially the lambdoid. The entire cranium is stated to have been enlarged in the cases reported by Adler and S. Solis-Cohen, while O'Connor's case showed some very atypical enlargements, or tumors, on the parietal bones.

The mucous membrane of the nostrils is frequently found hypertrophied. The sense of smell is very rarely affected. (Much impaired in Godlee's case.)

The tongue is broad and thick, and frequently of double its normal size, almost entirely filling the cavity of the mouth, so that the sides show indentations from the teeth. The upper surface of the tongue is often deeply corrugated, marked by deep lines and fissures, and the papillæ may be prominent and projecting. During speech the massive tongue gives the impression of weight and clumsiness. By the large tongue and the prognathism the speech is rendered thick, heavy, and often slow, while the labial and dental sounds are poorly articulated. The tongue is generally clean, but Long found it, in his case, always covered with a grayish-yellow coating.

The soft palate is often thickened, the uvula may be wide and long, even as large as a little finger (Boltz's case), and the epiglottis has been found considerably thickened. The larynx is enlarged, either as a whole, or in one or more sets of its cartilages. The ary-epiglottic ligaments have been found thickened (Gause's case), and the vocal cords hypertrophied (Fratrich's case). These conditions render the voice loud and harsh, the voice in women becoming masculine, and in men of much lower pitch.

The thyroid cartilage is often enlarged, as is also the

cricoid cartilage and frequently the hyoid bone. The submaxillary and other glands (lymphatics) of the neck may be enlarged (Adler's case). The thyroid gland may be normal in size, hypertrophied, cystic (Godlee's case), or so atrophied that it cannot be found.

The neck is short and thick, and the head leans forward, which with the cervico-dorsal kyphosis causes the long projecting chin to almost rest on the sternum.

Body.—Sooner or later, but almost invariably if the case is far enough advanced, the irregular formation and laying on of bone in the spinal column causes deformities of the spine. This deformity is almost constantly a cervico-dorsal kyphosis (Hare's case was dorsal), giving a humpback appearance very characteristic of this disease. Occasionally scoliosis is also present, and sometimes a compensatory lumbar, or dorso-lumbar, lordosis. The spinous processes of the vertebræ are frequently found abnormally prominent, especially the lower cervical.

The circumference of the chest is greatly increased, especially at the level of the ensiform cartilage, where it is the greatest. Laterally the chest appears flattened, while the antero-posterior diameter is often enormous. The sternum is generally widened and thickened, and projects outward, especially the hardened and enlarged xiphoid cartilage.

There are often prominent transverse ridges on the sternum, and there may be a hollowing or apparent sinking-in in the region of the manubrium, due to the irregular growth of the sternal segments. There may be triangular-shaped hollows at the sides of the sternum. A dulness on percussion is sometimes found at the upper end of the sternum, attributed by Erb and Verstraeten to an enlarged or persistent thymus gland, but though this gland has occasionally been found enlarged, Arnold has shown that the dulness is due to a thickening of the bone.

The clavicles are most enlarged at the sternal extremity, but the acromial end is also generally thickened.

The ribs are wide and very oblique, and at their junction with the more or less enlarged and ossified costal cartilages are generally found bony nodules, not unlike the rachitic rosary. The ribs are rendered oblique, and the lower ones are forced outward, by the great growth of the costal cartilages. The hardening of the ligaments and cartilages of the chest causes a peculiar stiff and constrained up-and-down, or out-and-in, motion of the lower part of the thorax during respiration, and the abdominal respiration is increased. In Packard's case the chest was very irregular, some of the ribs being very large and having numerous nodosities on their surfaces. In O'Connor's case there were distinct, circumscribed tumors on some of the ribs, and on each clavicle, at the sternal junction, was a sharp, inward projecting exostosis.

The abdomen is generally flattened and even appears retracted from the forward projection of the sternum and costal cartilages, though in Massalongo's case the abdomen is stated to have been "bulky and pendant."

The pelvis is generally enlarged in all parts, but the most marked hypertrophy occurs in the pubic bones, and in those at the symphysis pubis. The ilia seem to be wider apart, and the crests are broad and prominent. The penis is often enlarged, notably so in Cènas's case. The labiæ majoræ, as well as the labiæ minoræ may or may not be enlarged, the clitoris may be hypertrophied, and the vagina may be lengthened, but the uterus is generally small and atrophied.

Upper Extremity.—The shoulder-joint may be, but rarely is, much enlarged; the arm is small, at least not enlarged; the elbow-joint may be increased in size; the forearm is often enlarged at its lower third, especially just above and at the wrist; the wrist-joint is almost always large. The hand, widened, thickened, and often lengthened, is massive and enormous, and appears heavy and cumbersome for the relatively small arm to carry. The ends of the metacarpal bones and phalanges are enlarged, giving prominent joints. The skin of the hand and the subcutaneous tissues are greatly hypertrophied, so that the normal lines of the palm are greatly deepened, even to the appearance of fissures in the flesh. At the upper part of the hand, and over the metacarpal bone of the thumb, and on the ulnar border, the hypertrophy of the soft parts is excessive.

The fingers, by the growth of phalanges and soft parts, become of the same width and thickness at the tips as at the bases, giving the appearance called "sausage-shaped," which is a characteristic feature of this disease.

The above-shaped fingers, with the great thickness of the soft parts over the metacarpal bone of the thumb and on the ulnar border of the hand, with the exaggerated palmar lines, and the abnormal proportion of the hand to the size of the forearm, render the acromegalic hand a landmark not easily forgotten.

The fingers may appear somewhat flattened, and, according to Marie, there is often a manifest swelling at the articulation of the first and second phalanges.

FIG. 2.—Author's Case of Acromegaly. View of Enlarged Right Hand.

The nails are flattened, short, and sometimes widened, but always appear too small for the enlarged fingers, whose redundant flesh laps over them at the sides. The lateral borders of the nails sometimes curve upward when the hand is examined with the palm resting on the table (Marie). There are strongly marked longitudinal striations, sometimes even with ridges, and there may be transverse striations on the nails. They are also often brittle, breaking off or cracking easily.

In Cènas's case the nail of one finger fell off spontaneously and a new one developed.

Lower Extremity.—The thighs are generally not increased in size, although the condyles of the femurs are generally prominent and enlarged, which with the hypertrophy of the patellæ causes a marked enlargement of the knees. The upper ends of the tibiæ and fibulæ may or may not be enlarged, but the lower ends of the leg-

bones are generally found hypertrophied, causing prominent malleoli and large ankle-joints. The tendo Achillis is frequently prominent and hardened, or "rope-like" (Barclay-Symmer's case). The foot is described as "massive," "colossal," and "enormous." The bones of the feet are all enlarged and especially the os calcis, which projects backward, giving a marked prominence to the heel. The foot is thick and broad, with a prominent cushion of thickened skin and subcutaneous tissue on the external border, a characteristic feature of the foot in acromegaly. The toes are all large, but more especially the big toe, which is immense, and crowds the other toes together. The skin of the foot is redundant, hypertrophied, and thickened, especially on the toes, causing them to appear pushed back and turned up, throwing the skin into great folds on the upper surface of the toes. The nails of the toes present appearances similar to those of the fingers.

The projecting os calcis, covered with a cushion of hypertrophied skin and fat, with the pad of hypertrophied tissue on the external border of the foot, with the immense big toe pushing against the other toes, and the redundant skin, makes the acromegalic foot as prominent a landmark as the hand.

Asymmetry.—Acromegaly is primarily a symmetrical

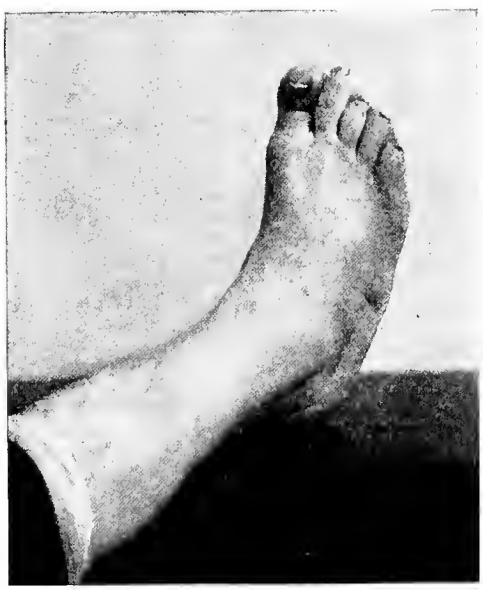

Fig. 3.—Author's Case of Acromegaly. View of Foot with Enlarged Toes.

disease, one part enlarging correspondingly with its fellow on the other side, but in many cases it is recorded that one side of the body was larger than the other, and that the right half of the body was more frequently the larger. In a number of cases data are given showing the growth to have commenced in one foot or one hand, or both feet or both hands, before other parts of the body were affected.

In fact, the growth probably generally starts in the hands and feet; later, the face and lower jaw are attacked; next, the lower ends of the arm and leg bones; next, the crests, tubercles, ridges, and eminences show growth, and about this time kyphosis develops, while lastly cartilages and tendons all over the body show bone-development. Besides the slight asymmetry of the two sides of the body, some atypical cases have occurred. In Kanthack's case the second toe of the left foot was enormously enlarged, far beyond the size of the other toes. In Cènas's case the face, head, hard palate, cheeks, lips, and tongue were much larger on the right side than on the left. All the fingers of the right hand were affected, but only the thumb and first finger of the left hand were enlarged; while, on the other hand, all the toes of the left foot were hypertrophied, and only the first, second, and fifth toes of the right foot. Also peculiar in this case was the fact that the fifth toes on both feet were larger than the third and fourth toes. Litthauer's case showed a slight talipes valgus.

Muscles.—At first the muscle-growth and muscular power are increased, and sometimes the development of the muscles may be very great, as in Virchow's case of the man Westphalen. Sooner or later, however, the muscles become atrophied in greater or less degree, and the muscular power is greatly diminished, even to the point of compelling the patient to remain in a sitting or reclining posture, or even forcing him to remain in bed. There may be recurrent attacks of great loss of muscular power, so that the patient must be assisted in his dressing, to be followed by periods of improved strength.

The muscles of the arms and legs at this period are flaccid and shrunken, and Virchow suggests that some of the kyphosis and scoliosis may be due to muscular debility. Some of the muscles may be found atrophied, as Boltz observed in his case the pectoralis major and the supra- and infra-spinatus in that condition. On the other hand, even while this condition of muscular weakness is present, there may be hypertrophies of certain muscles.

Mosler found the deltoid, supra-spinatus, rhomboideus, and biceps hypertrophied. In the writer's case, the supra-spinatus on the right side is so greatly hypertrophied as to constitute a large muscle-tumor, adding greatly to the kyphotic deformity.

Skin.—The subcutaneous fat may be increased or diminished, but later is generally found diminished, except, perhaps, on the diseased portions of the body. The skin on the affected parts is hypertrophied, and generally, especially where exposed, is olive-brown or yellowish in color. This yellow color is most marked on the face, and here most noticeably on the eyelids. The face may, however, be pale, or the nose may be red, as in Mosler's case. The skin may be dry and harsh from diminished sebaceous secretion. There is frequently increased perspiration, coming on with slight exercise, or even without exercise, either general or local on the diseased portion of the body, and especially frequent on the legs. This perspiration may have a disagreeable odor. The growth of the hair all over the body is generally increased. That of the head is thick, strong, and coarse, while the hair on the hands and forearms, and more especially on the legs, is greatly increased. There may be pigmentations on the skin, as in one of Marie's, in Barclay-Symmer's, and in Massalongo's cases. Litthauer speaks of the hands in his case as being of a light bluish color, while in the very interesting case of Cènas there were various-sized and -shaded violet spots on the hands, feet, legs, and body, with also a stripe-like line of vitiligo on the inner and back part of the thighs and legs. Growths of molluscum fibrosum frequently occur on the face, especially on the eyelids, and on the chest or back, generally pendulous in character. Multiple fibromata of the skin may occur, of the size of a millet-seed, and, according to Mosler, are especially apt to occur on the neck and in the hypochondriac regions. Fatty nodules may be found beneath the skin, and Litthauer reports, in his case, a 10 ctm. long and wide lipoma in the right supra-spinatus fossa.

Blood-vessels.—There are always vaso-motor disturbances of the affected portions of the body, as shown by the tingling, flushing, and local sweating. The flushing is often accompanied by a "burning pain." Besides these signs, which denote the dilatation of the small blood-vessels, there is a marked tendency to a dilated and varicose condition of the superficial veins, which is frequently found on the legs. Hemorrhoids are often present, and Graham's first case had a double varicocele, and profuse epistaxis may occur. O'Connor's case had enlarged veins of the neck, and Cènas's case had dilated veins on the forearm. Hare's case had a hemorrhage from the lungs. Mosler says that the arteries, radial and temporal, may show signs of beginning atheroma.

The blood has been many times examined, but, though the red corpuscles or the hæmoglobin may be decreased, no marked or constant changes have been found.

Internal Organs.—The lungs are normal, although there may be some dyspnœa, especially on exertion. The heart is normal, though often enlarged by simple hypertrophy; the pulse is generally normal, but tachycardia was present in Massalongo's case. Boltz found a soft systolic blowing sound at the apex in his case, probably hæmic, while in Holsti's case there was mitral disease. The liver and spleen are almost constantly normal in size.

The kidneys, as interpreted by the examination of the urine, are generally normal, although polyuria is often present, and albuminuria may be (writer's case). Sugar has been several times present and persistent, and two cases, at least, are recorded as having died of diabetes (Bury's and Thomson's). Peptone has been found in the urine in acromegaly in a few cases (Graham's first case, Cènas's case), being first discovered by Professor Bouchard.

Sight.—The eyes may be normal, but are frequently affected, in all degrees from occasional flashes of light (writer's case), or eye-blurs, to narrowing of the fields of vision and atrophy of the optic nerves, even to absolute blindness. Exophthalmos is often present, due both to actual enlargement of the eyeballs and to bone-growth in the orbital cavities. The pupils are generally normal in size but may be dilated (Long's and Ruttle's cases), and the reaction is generally as usual, though it may be slow to light but normal to accommodation. Nystagmus has been present in Boltz's case (rotatory nystagmus), in Long's case (which was blind) and in Packard's case (vertical nystagmus). Litthauer's case showed some strabismus divergens from insufficiency of both internal recti muscles, and Packard's case showed the same condition of the right eye. Marie says that we may early find, while vision is but slightly impaired, signs of optic neuritis caused by pressure. Narrowing of the visual fields has been found in all degrees even to bitemporal hemianopsia (Ruttle's, Packard's, Dulles's, Mosler's, Hare's, Boltz's, Schultze's, Strümpell's, Litthauer's, and Denti's cases). Optic atrophy, partial or complete, of one or both eyes, has frequently been found (Hadden and Ballance's, Ruttle's, Packard's, Hare's, and Boltz's cases, and in Long's case with total blindness). The retinæ may show venous congestion, the arteries may be small, or they may appear pale (Massalongo's case), or a congestion as of a neuro-retinitis may be present (Denti's case).

Hearing.—The hearing is not generally affected, but occasionally there has been decided deafness (Flemming's, Berkley's, and Osborne's cases). In two cases, at least, Barclay-Symmer's and the writer's, continuous and never-ceasing tinnitus aurium has been present, and Holsti's case complained of "rumbling and swashing" sounds in the ears. This ringing, or singing, in the ears is, in the writer's case, greatly increased on lying down, and often the patient, from this cause alone, cannot sleep at night but must remain in a sitting posture. The tinnitus in this case is increased on excitation as well as on lying down, and is often of a pulsating character, though of a fine, high-pitched tone, when he is at rest. He refers the tinnitus to the middle of his head. The drum may be hardened and thickened, and so stiffened as to be immovable.

Smell and Taste.—These are but rarely stated to have been affected, though in Godlee's case both were impaired, and in Brignini's case taste was slightly affected.

Nervous Phenomena.—A most constant symptom is pain in the head, which may be referred to any region, but is generally frontal or vertical, and in the writer's case was located in a small circumscribed spot, tender to pressure, over the region of the anterior fontanelle. This pain may be so mild that it is hardly complained of, or so severe, violent, and excruciating as to almost render the patient insane. Pain is often present in the joints, especially the knees, and is often severe in the fingers. Pain is frequently complained of in the chest, or abdomen, shooting around the body, or confined to one side, or it may be lumbar or sacral. Almost every case of acromegaly has pain, more or less constant and severe, in some part of the body, generally without any local cause. The pain in the head, however, I believe is often due to the enlarging pituitary body, though at other times probably to the dilatation of the blood-vessels of the brain; hence the increased headache on lying down, with the feeling of pressure, as has been the condition in several cases. Crepitations may be found in some of the joints, which, of course, would account for the pain there, though there is no swelling or signs of acute inflammation. Pain sometimes seems to centre at one of the small fibromata which occasionally develop in the skin.

Sometimes a peculiar nervous sensation is complained of, a sensation as of a nervous discharge, or electric shower, starting from the top of the head and passing quickly over the body to the feet. This is sometimes described as giving the sensation of the rolling of shot, hence it has been termed the "shot feel."

There are no marked or constant paræsthesiæ in acromegaly, though slight numbness or prickling of the affected parts is often found, most frequently in the fingers. The tactile sense of the fingers may be impaired, so that small objects cannot be readily handled, and sewing, knitting, or even dressing, becomes difficult. Where this condition is present it may become much improved, though the growth of the body and the advance of the disease may continue (Mosler's case). Of course, there is always clumsiness in the use of the fingers from the size alone. In Mosler's case the fingers would, at times, become pale and white, accompanied by severe pain, especially at night, evidently due to vaso-motor spasm. Formication of the affected parts may be complained of, and in Adler's case there was hyperæsthesia of all the hypertrophied parts, even slight pressure causing the patient pain. Ruttle's case had in the early part of the disease numbness all over the body. Permanent anæsthesia, analgesia, or impaired perception of heat or cold are certainly rare conditions in this disease.

The electrical responses of the muscles and nerves are rarely found abnormal.

The reflexes, both deep and superficial, are generally unimpaired. Occasionally the patellar reflexes are diminished, and sometimes absent on one or both sides (Packard's and Strembo's cases).

The mental faculties in the majority of cases are not impaired, but still in a large number of cases it is recorded that there was loss of memory, or apathy, or dulness and sluggishness of the mind, with or without a depressed state. Marie says that there may be a state of great good humor, but, on the contrary, the condition of melancholia is more frequent, and even suicidal tendencies may develop.

There may be great irritability (Packard's case), while there may be delusions, and the patient may be refractory and suspicious (Berkley's case). Pick's case showed at times decided insanity, and the patient finally committed suicide.

The writer's case, also, five years ago, for a period of four weeks, had frequent attacks of mental aberration, in which he not only attempted to commit suicide but showed homicidal tendencies.

Another interesting condition which seems to quite frequently occur in acromegaly is somnolency. An excessive example of this somnolency was Packard's case, which had three attacks, the first lasted for three weeks, and the second and third lasted even a longer time, the last becoming a profound stupor, so that for days at a time the patient lay with the eyes open, but could not be aroused. This patient, however, came out of this condition, and was able to leave the hospital. This somnolency is, however, generally only a drowsiness, with a constant desire to sleep.

Vertigo may occasionally occur, and be severe enough to cause the patient to grasp something for support, and also there may be attacks of syncope.

Ruttle's case, one year after the stoppage of menstrnation, was seized with a sudden attack of dizziness fol-

lowed by total loss of consciousness, and for three weeks it was thought that she could not live. Convalescence was slow, interrupted by relapses of agonizing pain and vertigo, with loss of consciousness. These attacks became less and less frequent, but loss of consciousness could be produced at any time by a playful slap on the shoulder, or by the slamming of a door.

Pituitary Enlargement.—Exactly how frequently pituitary enlargement takes place, of course, cannot be stated. A number of autopsies have been made in which the pituitary body was not enlarged. Clinically, I believe, a positive sign of the enlargement of this body to be impairment of vision. Out of thirty-three cases stating the condition of the eyes, eighteen had impairment of vision, of a greater or less degree, while in fifteen the vision was normal. In these eighteen cases there was pituitary enlargement, in all probability, with pressure on the optic tract or chiasma, and it is not at all improbable that some of the fifteen negative cases may later show loss of vision. In the cases in which tinnitus aurium is constantly present I believe it is often due to the pressure of the enlarging pituitary body, laterally, upon the cavernous sinuses. It also seems probable that the conditions showing sudden and serious brain trouble, as in Packard's, Berkley's, Pick's, Ruttle's, and the writer's cases, all of which point to cerebral tumor, are due to the first sharp pressure which the enlarged pituitary body exerts upon the brain, having perhaps suddenly burst from its bony moorings.

That in some cases one eye, in others both, and in still others the ears alone are affected, seems to me could be explained by the condition of the bony environments of the sella Turcica in the individual skull, the enlarging pituitary body tending to press in the direction of the least resistance. The middle clinoid processes being small the earlier will the pressure be exerted on the optic commissure, or if one of these processes is smaller than the other the pressure will first be exerted on that side, and one eye may be affected.

The following table shows the frequency of some of the most important symptoms of acromegaly · it has been compiled from thirty-four original articles of true cases of acromegaly, plus the abstracts of twelve cases for which I am indebted to Dr. Joseph Collins. These forty-six cases have been taken at random, and the completeness with which each case was reported varies greatly, but the statistics here appended may be of some value. In no case is a symptom considered as present or absent unless positively so stated to be ; consequently the frequency with which any symptom is present or absent must be compared with the number of cases reporting it, and not with the forty-six cases.

Important symptoms.	Number of cases.	Symptoms present.	Symptoms absent.
Hands enlarged	46	46	0
Feet enlarged	45	45	0
Lower jaw enlarged	37	36	1
Eyes affected	33	18	15
Kyphosis	23	21	2
Prognathism	17	15	2
Lower lip enlarged	27	26	1
Upper lip enlarged	18	15	3
Nose enlarged	29	29	0
Tongue enlarged	31	31	0
Voice changed	24	23	1
Taste impaired	14	2	12
Smell impaired	11	1	10
Hearing impaired	20	4	16
Ears enlarged	23	13	10
Face elliptical	20	18	2
Forehead low	10	9	1
Supra-orbital ridges large	16	13	3
Malar bones enlarged	21	17	4
Superior maxillæ enlarged	9	4	5
Exophthalmos	5	5	0
Eyelids enlarged	10	6	4
Cranium enlarged	10	3	7
Clavicles enlarged	21	18	3
Scapulæ enlarged	9	4	5
Sternum enlarged	12	10	2
Costal cartilages enlarged	8	8	0
Lordosis	7	4	3
Scoliosis	11	8	3
Pelvis enlarged	7	4	3
Generative organs enlarged	7	4	3
Arms enlarged	19	4	15
Forearms enlarged	12	5	7
Fingers sausage-shaped	9	9	0
Nails short and broad	16	14	2
Wrist enlarged	10	9	1
Crepitation in joints	8	3	5
Legs enlarged	19	10	9
Knees enlarged	5	5	0
Patellæ enlarged	8	7	1
Ankles enlarged	5	5	0
Varicose veins of legs	8	7	1
Albumin in the urine	19	2	17
Sugar in the urine	24	4	20
Skin yellow	8	7	1
Increased growth of hair	12	8	4
Paræsthesiæ	21	16	5
Muscular atrophy	12	11	1
Muscular hypertrophy	4	4	0
Increased strength	6	4	2
Diminished strength	22	20	2
Increased perspiration	15	13	2
Pain in some part of body	17	16	1
Headache	27	23	4
Somnolency	9	8	1
Intellectual faculties impaired	27	16	11
Increased appetite	20	10	10
Increased thirst	16	9	7
Polyuria	10	6	4
Constipation	9	8	1
Dyspepsia	6	2	4

Pathological Anatomy. — Eleven autopsies, at least, have been made upon cases that have died while suffering from acromegaly. Three of these cases were not diagnosed until after death, and after the autopsical reports had been on record for some time, viz.: Brigidi's, Henrot's, and Thomson's. The other cases are those of Klebs, Broca, Virchow (Fraentzel), Holsti, Bury, Arnold, Sarbo, and Gonzalez Cepeda.

Seven of these cases showed either a hypertrophied pituitary body (Brigidi's, Klebs's, Broca's, Gonzalez Cepeda's, Thomson's) or a tumor excavating the sella Turcica (Henrot's, Bury's). Brigidi's case furnishes a skeleton very typical of this disease. Henrot's case has been considered to be a case of myxœdema, but the positive bone enlargement certainly proves it to have been a case of acromegaly. In this case there was mucoid degeneration of the pneumogastric and glosso-pharyngeal nerves, of the brachial plexus, and of the ganglia and cord of the great sympathetic, while a tumor was located in the region of the pituitary body.

Thomson gives a very careful description of the skeleton of a case of acromegaly, the autopsy and history of which had been reported by Dr. D. J. Cunningham under the title of "A Large Subarachnoid Cyst Involving the Greater Part of the Parietal Lobe of the Brain."

The pituitary body in this case was greatly hypertrophied, being four or five times its usual size, and though soft and pulpy had caused considerable enlargement of the sella Turcica. The brain itself was also enlarged.

Klebs found not only enlargement of the pituitary body, but also a large thymus gland. The brain in this case was also enlarged, and there was thickening of the cranial nerves, especially the oculo-motor and optic.

Broca made the autopsy and described the skeleton of one of Marie's first cases. He also found an enlarged pituitary body.

Virchow showed and described the skeleton of the case of Fraentzel. In this case the pituitary body was normal.

Holsti found in his case an enlarged brain, and a large, pulpy pituitary body. He also considered the cranial nerves to be broader than normal. There was a fatty growth in the region of the thymus.

In Bury's case there was a large tumor at the base of the brain, a glioma, excavating the sella Turcica, pressing upon the optic chiasm, and extending to the cerebellum. There were traces of what may have been a persistent thymus.

Arnold gave a very exhaustive and careful description of the skeleton of Friedreich's case, viz., one of the brothers Hagner. Marie does not consider these brothers to have had acromegaly at all, and gives several valid reasons for his opinion, but I cannot but think with Virchow, Arnold, Mosler, and Erb that they did suffer from acromegaly. They are, however, very atypical cases, and there was unquestionable elephantiasis of the legs present. The pituitary body was normal in Arnold's case.

Sarbo found in his case, which had had syphilis, evidence of peri-encephalitis chronica. The pituitary body was normal.

Gonzalez Cepeda found an enlarged pituitary body.

Such are the special points of interest in these several cases.

The constant pathological findings in acromegaly are enlargement of the bones of the hands and feet, and almost invariably enlargement of the lower jaw. The ends of the long bones are very generally found enlarged. The pituitary body, as we have seen, may or may not be enlarged, but if we take into consideration the number of cases still living that have shown positive signs and symptoms of pituitary enlargement, we cannot but agree with Marie and Broca that it is a pathological finding of great importance.

On the other hand, an enlarged thymus gland (Klebs and Erb) or the possible fragments of a persistent thymus have been found so infrequently as to present no pathological importance in this disease, but is rather a curiosity. As to the thyroid gland, which Marie at first considered to be almost always atrophied in this disease, though still a factor of great interest and careful examination, it has not shown any very constant condition, either clinically or pathologically. It may be enlarged and hard (Holsti), enlarged and cystic (Bury), normal (Virchow, Sarbo), or diminished in size.

The lungs are not affected (Sarbo found phthisical processes in the lungs of his case); the heart may or may not be hypertrophied; the liver and spleen are normal (both diseased in Holsti's case, liver enlarged in Bury's case). The kidneys may or may not be found diseased.

The nerves, as stated above, may be affected, and Marie thought that there was constant hypertrophy of the cord and ganglia of the sympathetic system. The spinal cord does not seem to have been carefully examined. Syringomyelia was present in Holschewnikoff's case (if indeed this was a case of acromegaly) and mucoid degeneration in Henrot's case. The cerebrum has been found increased in weight, which is due to a general growth, and Klebs found that there was an increase of the neuroglia cells, but in direct proportion to the general enlargement of the brain-substance.

There is widening of the blood-vessels and thinning of their walls, especially of the veins, as was first pointed out by Klebs and Erb. The valves of the veins have been found enlarged. The thinning of the vessel-walls weakens them, especially the veins, and, as a result, we frequently find a varicose condition of the veins of the legs, hæmorrhoids, and enlarged veins of the arms, neck, or head. The epistaxis noticed in two cases (Osborne's, Barclay-Symmer's) may have been due to the same cause. Klebs found an increase of the cells in the walls of the blood-vessels, which he considered to be the cause of the widely distributed new growths of blood-vessels, or angiomatosis, and this the cause of the tissue hypertrophy. Von Recklinghausen, however, found no such indication of growth of new blood-vessels. The muscles at the time of death, unless the patient dies early in the disease from some intercurrent affection, are found very generally atrophied, although there may be local hypertrophies. Certain muscles, especially the deltoid or supraspinatus, may become markedly hypertrophied, forming veritable muscle-tumors. One side of the body, most frequently the right, may and often is, larger than the other, both in the size of the bones and of the soft parts, but more especially the latter. Von Recklinghausen, with Marie and Mosler, does not agree with Virchow in calling an enlarged extremity a "partial acromegaly."

The subcutaneous fat may be increased or decreased in thickness, but in the later stages it is probably nearly always decreased. The skin is hypertrophied over the affected portions of the body, sometimes enormously. All the layers of the skin take part in this thickening.

Elephantiasis has occurred in three cases—the brothers Hagner and in Lombroso's case. In the former cases the legs were affected; in the last case the forearms and face.

Von Recklinghausen says that fibromata and neuromata of the skin can be present in considerable number in acromegaly. Molluscous growths are of frequent occurrence.

Now turning to a critical survey of the skeleton, we find that we are indebted to Broca, Virchow, Arnold, and Thomson for the careful study of the condition of the bones found in this disease. Broca says that the enlargement of the bones is in the extremities, and at the ends of the bones. He also says that it is the spongy tissue of the short bones and flat bones that is affected, and the epiphyses of the long bones. Holsti, however, found the compact substance of the bones thicker than normal. This growth of bone is an hypertrophy, the bone growing from the periosteum, and in the medullary spongy tissue at the ends of the long bones. The growth in the early part of the disease seems to be more especially confined to the periosteum; later, the apophyses and epiphyses become affected; next, the crests, tuberosities, and eminences enlarge and grow in the direction of the muscular action. The tendons are often found in deep grooves or bony canals, and the foramina for the nutrient arteries are enlarged.

Osteophytes may be found in the joints, especially over the wrist- and ankle-joints, and the cartilages show bone developments.

The spongy ends of the long bones now become more compact, the architecture changing, the bone-cells increasing, and eburnation taking place. The ends of the bones in Sarbo's case showed condensing osteitis. As Arnold showed, the long bones may apparently lengthen by the laying on of bone at the extremities, while the shaft is not at all affected; and von Recklinghausen has suggested that the giant appearance of some cases of acromegaly could be due to the late union of the epiphysis with the shaft, the epiphysis becoming widely separated from the shaft by the new bone, thus causing a pronounced lengthening.

Before turning to a more careful survey of the various bones, it must not be forgotten that the duration of the disease must be considered when examining any particular skeleton, as widely different conditions of the bones are found at different stages.

The bones of the cranium are often found thickened (Thomson's case had thickening of the cranial bones varying from 6 to 12 mm.) and hardened, true bone developing in the diploë, as well as the external and internal plates becoming hypertrophied. The ridges and crests for the attachment of muscles and fasciæ are more prominent, while the occipital protuberance has been found as a spicula-like outgrowth, an exostosis. The parietal eminences are sometimes abnormally prominent, as are always the superciliary ridges, the latter being due not only to the dilatation of the frontal sinuses (Broca), but also to the thickening of the plates of the frontal bone in this region (Thomson). The sphenoidal sinuses have been found dilated (Broca), and also the antrum of Highmore.

The lengthening of the face is largely due to the increase in the vertical diameters of the superior and inferior maxillæ. The malar bones are almost always prominent and projecting, the ridges for muscle attachment being pronounced. The orbital cavities are large, widened transversely, with the borders prominent, especially at the external angle. Some of the sutures of the bones may be obliterated, as in the articulations of the superior maxillæ and malar bones in Thomson's case. The external auditory canal may be increased in length by the growth of the cartilages and the formation of new bone. These canals may also be found narrowed by

exostoses. The glenoid cavities are increased in size, probably due, as Thomson suggests, to the large size of the condyles of the lower jaw. The eminentia articularis may disappear, giving an opportunity for the condyle to come forward, thus adding to the prognathism caused by the growth of the lower jaw.

The lower jaw is described as massive, the chief growth being in the body, which is found lengthened and widened, especially at the symphysis, with the mental process prominent and projecting. The alveolar process is widened and thickened, and the rami also may partake of this growth, while the angle of junction between the body and rami becomes more obtuse. In Thomson's case the coronoid processes extended upward more than one-third higher than normal. The growth of the alveolar process is rarely participated in by the teeth (except Cènas's case), they remaining normal in size, so that, the alveolar cavities enlarging, we frequently have spontaneous falling out of the teeth.

The projecting lower jaw and lengthening of the chin, it must be remembered, are not always found in acromegaly, as undoubted cases have occurred in which these conditions were absent. This growth of the lower jaw being present, on the other hand, with enlargement of the hands and feet, is, I believe, pathognomonic. Thomson found the margin of the foramen magnum surrounded by irregular protuberances of spongy bone.

Whenever an enlarged pituitary body has been found the sella Turcica has been found deepened and enlarged in all directions, due to the bone wasting from pressure.

The hyoid bone may be enlarged and its ridges very prominent.

Changes are always found in the spine, the degree being due to the age of the disease. The bodies of the vertebræ are enlarged, and especially from the laying-on of bone on the anterior part. In the cervical and dorsal regions the increase in bone is often restricted to the upper part of the inter-articular cartilages, while in the lumbar region the increase of the bone is more general. The spinous processes are enlarged, and the transverse processes may be. The irregular thickening of the inter-vertebral cartilages, with the irregular growth of the bodies of the vertebræ, sooner or later causes deformities of the spine, viz., kyphosis, lordosis, or scoliosis (Virchow-Fraentzel case showed alternate right and left scoliosis in the dorsal region). Anteriorly the spine may appear as one bone, due to the growth of spongy bone in the anterior ligament, forming bridges of bone connecting the vertebræ together (Virchow-Fraentzel's, Thomson's).

The sternum is enlarged and thickened, and the ensiform cartilage is ossified, generally projecting outward. Often very large transverse ridges are found on the sternum, also a hollow or depression may be seen at the upper part, due to to the manubrium not enlarging relatively to the body of the sternum.

The costal cartilages are large, with more or less bone-formation, and with prominent cartilaginous or bony nodes at the junction with the ribs, simulating the rachitic rosary. The bone-growth in the costal cartilages may give an apparent great widening of the sternum. The ribs are wide and thick, and by the faster growth of the costal cartilages become abnormally oblique.

Small bony tumors have been found on some of the ribs (O'Connor's case).

The clavicles are always found enlarged at their extremities, but more especially at the sternal end. A sharp, inward projecting spicula of bone, exostosis, was found in O'Connor's case.

The scapulæ are generally found enlarged, and more especially is the spine large and thickened. Thomson found the glenoid articular surface enlarged, due to the ossification of the glenoid ligaments.

The articular surfaces of all the long bones may be roughened (Broca, Thomson), and there may be exostoses, spongy growths, and osteophytes in and around the joints. The humerus may be thus affected, but is infrequently enlarged. The radius and ulna, if the case is of long standing, are found enlarged at the lower extremities, and, perhaps, at the lower third of the shafts. As before stated, the ridges and protuberances are enlarged on all of the long bones, if the disease is at all advanced. The enlarged lower extremities of the radius and ulna, with the widened and thickened carpal bones, give the large wrist and hand. The metacarpal bones and phalanges are widened and thickened, the former especially at the head, and the latter at each extremity, causing the prominent joints. The phalanges are generally equally affected, but one set may be more affected than the other.

The pelvis is almost always enlarged, especially the pubic bones. The symphysis is thick and deep, and the crests of the ilia are wide and prominent. Thomson found the ileo-pectineal line on the right side raised into a prominent crest, and the acetabula enlarged by partial ossification of the cotyloid ligaments.

The femurs are only enlarged at the lower extremities, viz., the condyles, as are also the heads of the tibiæ and fibulæ and the patellæ.

The malleoli are frequently found enlarged. Of the tarsus the os calcis is the most affected, growing backward into a prominent projection. The metatarsal bones and the phalanges are all enlarged similarly to those of the hands. Thomson found several of the phalanges of the toes ossified together.

Etiology.—Thus far there has been no positive cause found for the occurrence of this disease. Various theories have been offered, one of the most interesting of which is that by Freund. He suggested the probability that acromegaly was a disease of puberty or thereabouts, *i.e.*, a disease of development, a possible returning to type, the large hands and feet, projecting jaw, and retreating forehead being certainly very suggestive.

Klebs partially supported this theory, but laid great stress on the enlargement of the thymus gland. Virchow, however, does not support this theory of Freund at all. Professor Freund said that this anomaly of development had some relation to the condition of the developmental organs, to sexual development, and that the early cessation of menstruation or early loss of sexual power caused acromegaly.

This theory is not supported by facts.

The ages at which forty-six cases were discovered and reported are as follows:

2 cases in second decade of life (10 to 20 years). Cènas's case and Mennig's daughter (Virchow-Fraentzel).
6 cases in third decade of life (20 to 30 years).
8 cases in fourth decade of life (30 to 40 years).
20 cases in fifth decade of life (40 to 50 years).
8 cases in sixth decade of life (50 to 60 years).
2 cases in seventh decade of life (60 to 70 years).

It is here seen that two and one-half times as many cases first come for treatment, or are discovered, between forty and fifty as at any other decade of life. Fourteen of the 20 cases which first came in the fifth decade (from forty to fifty), were between forty and forty-five years old.

Of 39 cases giving data of more or less successfully estimated age at which the disease started:

2 are congenital (Cènas' case and Mennig's daughter).
4 began in the second decade (10 to 20 years).
16 began in the third decade (20 to 30 years).
12 began in the fourth decade (30 to 40 years).
5 began in the fifth decade (40 to 50 years).

This shows nearly three-fourths of these cases to have begun between the ages of twenty and forty, and 33 of the 39 cases after twenty years of age.

By the above facts I fail to see how the Freund theory is tenable.

Sex does not seem to bear any special relation to the disease. Out of 50 cases, 27 were women and 23 men.

Of 13 women who were at an age at which menstruation does not normally cease, 9 had cessation of menstruation as a first symptom, while 4 menstruated for a time after the beginning of the disease, but soon stopped.

One case, a woman aged fifty-three (Harris's case), had had acromegaly for twenty years, but had a child at forty-three years of age.

Of 12 cases of men in which it is mentioned, 10 had diminished or lost sexual power, while 2 were normal in this respect.

I believe these phenomena are only symptoms, and cannot attribute to them, as does Freund, a causative relation to this disease.

While the cessation of menstruation is unquestionably an early and a very frequent symptom, it is not constant, and is only a symptom.

The loss of sexual power in the male is a gradual loss, diminishing with the progress of the disease. Virchow and Verstraeten both find no causative relation between the generative organs and acromegaly.

Klebs and Fritsche found an enlarged thymus gland in their case, while Erb found, in three cases, a dulness at the upper part of the sternum which he attributed to an enlarged thymus. Klebs at first thought that this gland, being enlarged or persistent, might have something to do with the increased growth of blood-vessels and tissue. Later autopsies, however, have proved this gland to be generally absent, and Arnold has shown, as before mentioned, that the thickening of the sternum in the region of the manubrium could give the dull percussion note sometimes heard. These facts preclude the enlarged thymus from the position of an important factor in the etiology of this disease.

Of 19 cases giving data on this point, 15 are recorded as having no dulness at the top of the sternum, while in 4 cases dulness was found.

The thyroid also has come in for a share in the etiological interest of this disease, but its condition is found to be so varied that it is only of symptomatic importance. Out of 32 cases making record of the condition of this gland, it was atrophied 14 times, enlarged 8 times, and normal 10 times.

On the other hand, of more than ordinary interest is the pituitary body, which has so many times been found enlarged in autopsies of this disease, and so frequently can be diagnosed as being in that condition in living cases. Of 33 cases of acromegaly reporting the condition of the eyes, 18 had eye-changes, more or less severe, and 15 at the time of reporting had no eye-changes, while 4 had ear-trouble. Headache, sometimes violent, is a very frequent and almost constant (23 times out of 27 cases) symptom. Though acromegaly can surely occur without enlargement of the pituitary body, still we must acknowledge that it stands very close to some etiological factor (angiomatosis, or neurotic origin).

Nativity does not play any important part in the causation of acromegaly, although a number of the cases reported in America have been Germans. One case (Berkley's) occurred in a negress; hence the colored race is not exempt.

As to the hereditary history in 46 cases, rheumatism was stated as present in the families of 2 of them, 3 had tuberculosis in the family, and 2 had a neurotic family history.

The Hagner brothers, atypical cases of acromegaly combined with elephantiasis of the legs, were similarly affected.

The daughter of Mennig (Fraentzel's case of acromegaly, whose skeleton was exhibited by Virchow) had the disease; and Fratrich says that the father of his case had large hands like the patient.

As to the personal history of 46 cases, rheumatism was stated to have been present 5 times, 1 had had asthma, 1 pleurisy, 1 a winter bronchitis, 1 pneumonia, 1 abscesses of each hip, and 2 had had a severe typhoid fever, from which the disease could be dated, while 1 case (Massalongo's), when twenty-two years old, had "loss of consciousness and delirium, which lasted forty days, called cerebral fever."

Klebs is inclined to refer this disease to the vascular system, regarding it as an angiomatosis, and Gauthier agrees with him. We certainly frequently find varicose veins, sometimes hemorrhoids, and occasionally varicocele and epistaxis, but we do not find blood-vessel growths, and von Recklinghausen could not find indications of actual growth of new vessels. There is frequently a burning and flushing of the affected parts, showing an increased blood-supply, due to the dilatation of the blood-vessels, probably of vaso-motor origin. The blood, though many times examined, has shown nothing of moment.

Von Recklinghausen believes that this disease is of neurotic origin. He says that acromegaly may be caused by vaso-motor disturbances which may cause neurotic hyperæmia, going on even to inflammation of the nerves. This would explain the condition of a few of the nerves found at some of the autopsies. The widening of the blood-vessels and the thinning of their walls, especially of the veins, can well be the result of such abnormal innervation of the vessels. He also thinks that the disturbance of menstruation can be explained by this general angioneurosis. It is also known that disturbed nervous conditions can cause hypertrophies of both bones and soft parts.

On the other hand, except the conditions in the brain due to direct pressure from an enlarging pituitary body, but few signs or symptoms referable to the nervous system are found. In forty-six cases some mild paræsthesiæ were stated as present sixteen times, such as numbness, prickling or formications, generally in the hands, sometimes in the feet or ears. The "shot-feel" was twice mentioned, once vertigo, and twice fainting attacks. Sensibility and electrical conditions were always normal. Six times it was stated that the patellar reflexes were diminished or absent. Hence, in these forty-six cases there was no serious lesion of the nervous system, except the trouble caused by the pituitary body. Holschewnikoff's case of syringomyelia, with enlargement of the bones (acromegaly ?), was probably a mere concidence. Although, then, acknowledging that we have not yet discovered the origin of this disease which affects nerves, blood-vessels, glands, bones, cartilages, tendons, muscles, skin, and nails, I believe that the spinal cord, especially the vaso-motor centre, and the sympathetic system furnish the most promising field for future research.

Diagnosis.—This disease must be diagnosed from myxœdema, gigantism, erythromelalgia, elephantiasis, leontiasis ossea, chronic rheumatism, syringomyelia, rachitis, osteitis deformans, arthritis deformans, *osteoarthropathie hypertrophiante pneumique*, local hypertrophies, and adiposis dolorosa.

More than one case of acromegaly has been described under the name of *myxœdema*. Myxœdema is an affection associated with an increase of the subcutaneous fat and connective tissue, and is characterized by a mucoid deposit in the skin and some of the internal organs, with marked changes in the thyroid gland and in the sympathetic nerves. There is swelling of all parts of the face, tongue, throat, and larynx, but generally there is no pitting. The hands become large and clumsy, and there may be pain in the joints and head. There may be loss of hearing, choked disk, and impaired mental faculties, even to dementia in the last stages.

The principal clinical differences between these two diseases are as follows:

Myxœdema.	*Acromegaly.*
1. About eighty per cent. of all cases are women.	1. Both sexes are about equally affected.
2. Occurs most frequently between the ages of forty and fifty.	2. Begins most frequently between the ages of twenty and forty.
3. Bones are never enlarged.	3. Bones are always enlarged.
4. Face has the appearance of a "full moon" (Sir William Gull).	4. Face is oval or elliptical.
5. The ends of the fingers are swollen and clubbed.	5. The ends of the fingers are the same size as the bases, *i.e.*, "sausage-shaped."
6. The skin is pale, waxy, puffy, boggy, and shiny.	6. The skin is yellowish, wrinkled, and hairy.

Gigantism, or giant growth, is distinguished from acromegaly by the fact that in the former there is symmetrical and general growth all over the body; the cranium grows as much as the facial bones, and the face does not look too large for the head, nor the head too large for the body, as is the case in acromegaly.

In gigantism the ends of the bones are not enlarged out of proportion to the size of the shaft, and the hands and feet are not enlarged out of proportion to the arms and legs. The bones increase in length as well as in width and thickness, and that symmetrically, and the whole growth of the body is in proportion, as in a normal individual, all of which is quite the contrary in acromegaly.

In gigantism there is no projection of the lower jaw, there are no nervous phenomena, there are no eye and ear symptoms. The nose, ears, lips and tongue are not increased in size out of proportion to the size of the head, face, and mouth. The foot in giant growth is in normal relation to, or even too small for the length of the body, according to Virchow. He says, normally, the foot is one-sixth the body's length, and in gigantism the height is more than six times the length of the foot, while in acromegaly the height is always less than six times the length of the foot.

In acromegaly the bone-growth and hypertrophy are always at the ends or extremities of the long bones, and never is the shaft lengthened, although an apparent lengthening may take place due to a laying-on of bone at the ends, producing an actual increase in measurement, but without growth of the shaft.

In *erythromelalgia*, a vaso-motor neurosis of the extremities, there may be some increase in the size of the hands or feet. There may be, according to Weir Mitchell, severe pain of the part, and there is always an impaired blood-flow, giving burning sensations, local redness, and even cyanosis, often in patches or spots. Cènas's case, with its peculiar pigmentation, is the only case of acromegaly that has markedly simulated erythromelalgia. In the latter disease, however, there is no enlargement of the bones or soft parts of the face, no eye symptoms, no marked change in the speech, and the hand itself is unlike the acromegalic hand, the fingers are not sausage-shaped, but smaller at the tip than at the base.

Elephantiasis arabum is a hypertrophic disease of the skin and subcutaneous tissue, located generally in one, occasionally in two extremities of the body. There is generally a history of several attacks of local inflammation of the part affected, followed by a continuous growth and hypertrophy of the skin, until an enormous size is reached. The hypertrophied skin falls in great folds, fissures form, and the part becomes one immense, homogeneous mass, without form or shape, and sections show a fibrous tissue without nerves or blood-vessels.

How different is this picture from that of acromegaly, where all of the extremities are enlarged, or at least one after the other, and the parts never lose the normal curves, prominences and hollows, and, though large, preserve their normal contours.

Again, in elephantiasis the bones are not enlarged, the skeleton is not affected, and the nervous, facial, and cerebral phenomena are not present.

Leontiasis ossea is the name given by Virchow to the condition where osteophytes, or bony tumors, are formed on the face and cranium. These bony tumors are of irregular distribution, and produce great deformity and asymmetry. There is no hypertrophy of the limbs. Though this disease has been several times mentioned in the diagnosis of acromegaly, I fail to so see how it could be confounded with the general constitutional disease of acromegaly with its manifold signs and symptoms.

During the first stages of acromegaly one of the frequent symptoms, and often a prominent one, is joint-pain, which at this stage might confuse the diagnosis with that of *chronic rheumatism*. The joints at this time are tender to the touch, but are not reddened or swollen. The pain is not permanent in any one or two joints, and ankylosis does not take place, although later crepitations are often present, and some contractures of the fingers may be found, as in Cènas's case, due to the flexor tendons not growing as rapidly as the bones. As soon as the hands, feet, or face begin to enlarge, the diagnosis from chronic rheumatism becomes plain.

Syringomyelia is a disease of the nervous system, characterized by a "gliomatous new formation about the central canal of the spinal cord, with cavity formation" (Osler).

This disease generally begins before twenty, or in early adult life, and in its slow development and long duration simulates acromegaly. After the complete development of either disease, however, "the amyotrophic paralysis, with retention of tactile and loss of thermic and painful sensation" (Osler), on the part of the syringo-myelia, and the enlarged extremities, the formation of the face and chest, to say nothing of the pituitary enlargement, on the part of the acromegaly, render the diagnosis easy.

Holschewnikoff has reported a case of syringomyelia, with the formation of gliomata in the spinal cord, together with degeneration of some of the peripheral nerves, in which there was decided bone-growth of the extremities, in fact an acromegalic condition.

Rachitis is a disease of childhood, or rather babyhood, occurring most frequently in children under three years of age. This alone would exclude the possibility of confusion with acromegaly, except in congenital cases. Rickets is pre-eminently a disease of impaired bone-formation, as instance slow development or entire absence of the teeth, and impaired growth or softening of the bones, while acromegaly, on the other hand, is pre-eminently a disease of increased bone-formation.

The ends of the bones, especially the epiphyses of the wrist, unquestionably are enlarged in rickets, while the hands and feet may be flattened and apparently widened, but there is no increase in the thickness of the hands or feet. The bones of the head show no malformation, except flattening and lengthening of the cranium with projection of the occiput, and the softened spots. This causes the cranium in rickets to appear too large for the face, while in acromegaly the face appears too large for the cranium.

Also in rickets we find deformation of the pelvis, and if the child creeps, deformities of the arm-bones, and if he walks, bending of the leg-bones. This is quite different from acromegaly, where we have widening, hardening, and general growth of the bones. Softening of the ribs causes a sinking in just before the junction with the cartilages, giving the formation of the rachitic rosary, which from another cause we find in acromegaly. Kyphosis, when it occurs in rachitis, is in the dorsal region, while in acromegaly it is almost invariably in the cervico-dorsal region. It is thus seen that it is hardly possible to confound the one disease with the other.

The diagnosis between the *osteitis deformans* of Paget and acromegaly is generally not difficult.

The following schedule will show some of the marked differences:

Osteitis Deformans.	*Acromegaly.*
1. Rarely occurs before fifty, never before forty years of age.	1. Very generally begins before forty years of age.
2. The long bones are the ones primarily affected, rarely are the hands or feet affected.	2. Hands and feet are enormous, rarely are long bones much affected.
3. Long bones are often curved, giving great deformity.	3. Long bones are normal in shape, possibly thickened at the extremities, but are never curved.
4. Often one limb or one bone is affected long before another limb or bone.	4. Hands, feet, arms, and legs generally nearly symmetrical.
5. The cranial bones are affected, rarely the facial.	5. The facial bones are affected, rarely the cranial.
6. Lower part of face is narrow, giving a triangular appearance to the face.	6. Lower part of face is broad, giving an elliptical appearance to the face.

The above gross, to say nothing of more minute differences, will generally readily make the diagnosis of osteitis deformans from acromegaly.

Arthritis deformans, perhaps, approaches more nearly than any other bone disease to the external conditions found in acromegaly. In arthritis deformans decided changes take place in the articular tissues, accompanied by pain, with sooner or later great deformity and ankylosis of the joints. Tender nodules may appear in the muscles, while the muscles themselves become atrophied.

The disease is apt to attack the same joints on both sides of the body symmetrically, but soon spreads to all of the joints. The hands are thin from the wasting of the fat and muscles, but the ends of the phalanges and metacarpal bones may be enlarged and nodular. The fingers are more or less flexed and turned toward the ulnar side of the arm, while the joints of the hand are all stiff and more or less completely ankylosed. How different is this condition from the acromegalic hand!

Within the joints bony or cartilaginous protuberances are found on the outer surface of the epiphyses in arthritis deformans, while in acromegaly we may find osteophytes at the ends of the bones, as in the Virchow's skeleton, or the bony growths found in the joints of Thomson's case. Outside of this similarity in the joints between these two diseases there is no agreement of symptoms or appearances. The hypertrophy of the soft parts of the hands and face, with the enlargement of the bones of the face, with the cervico-dorsal kyphosis, enlarged tongue, changed voice and eye changes, if present, will all or any of them make the diagnosis from arthritis deformans. Schulz has reported a case of acromegaly associated with arthritis deformans.

In January of 1890, in the *Revue de Médicine*, appeared an article by Marie in which he described a new disease, and which he named *osteo-arthropathie hypertrophiante pneumique*. This disease, as its name implies, is characterized by a disease of the lungs with an enlargement of the extremities, and therefore simulates acromegaly. The affection of the lungs may be an empyema, a bronchitis, or neoplastic formations, and, according to Mosler, there is present a micro-parasite, the absorption of the products of which into the blood and the deposit of these in the joints produces a hypertrophic inflammation. The hands are enlarged, but principally in the joints and the ends of the fingers, the middle of the hand not being attacked. The elbow-, shoulder-, and knee-joints are all affected, and there is always more or less impaired motion. The wrist-joint is large, the hand proper not much enlarged, while the fingers are increased in size, especially the last phalanx, but the soft parts are not hypertrophied. The appearance of the finger-nails is also quite characteristic of this disease. They appear too large for the fingers, spreading out at the sides, and even curving over the ends of the fingers, often giving the appearance of the beak of a bird, while the enlarged ends of the fingers have caused them to be likened to drumsticks. Turning to the acromegalic hand, with its immense thickening of the hand proper, hypertrophy of the soft parts, equally enlarged phalanges, sausage-shaped fingers, small nails, much too small for the fingers, one might make the diagnosis by the hand alone. The bones in osteo-arthropathie pneumique are enlarged, but not the soft parts, while in acromegaly both are enlarged. In the former disease dorso-lumbar kyphosis may be present, while in acromegaly the kyphosis is cervico-dorsal. In Packard's case of osteo-arthropathie pneumique, however, the kyphosis was cervico-dorsal (*Am. Jour. of the Med. Sciences*, June, 1892).

The feet and toes in this disease are affected similarly to the hands. The face presents a different appearance from that of acromegaly; it is more rounded, the lower jaw is very rarely enlarged (occurred in Packard's case), prognathism does not occur, the face appears small, the soft parts are not hypertrophied, and the lips and tongue are normal in size.

Virchow proposes to call the *local hypertrophies* which are occasionally met with, where one hand, or one foot, or one finger or toe, or several fingers or toes, are involved, "partial acromegaly." Marie and Mosler do not accept this classification of these local hypertrophies, even if the bone of the part is enlarged, and I agree with them that these simple hypertrophies should not be confounded with the distinct disease of acromegaly. Marie says: "Let established names as macrodactylia and macropodia and unilateral macrosomia, etc., be preserved, as the names for these peculiar localized hypertrophies."

These local enlargements of one extremity, or one finger, or one toe, are generally congenital, though they may increase in growth at the time of puberty, and the part is generally increased in length. One side of the face may be affected, involving bones and soft parts, including the tongue, tonsil, and palate on that side, but whatever the enlargement there is no symmetry.

One more disease remains to be diagnosed from acromegaly, viz., the disease recently described and named by Dr. F. X. Dercum, *adiposis dolorosa* (*American Journal of the Medical Sciences*, November, 1892). In this article he reports three cases, all women, where there was an enormous growth of fat. In the first case it was especially marked on the arms and body, where the fat fell in great folds. The second case showed an immense development of fat all over the body, but unevenly distributed in lumps and in folds; she had headache, great weakness, and cardiac dyspnœa, but no mental impairment, and sight and voice were not affected. The autopsy of this case showed an indurated thyroid gland, with some deposit of calcareous matter, and there was œdema of the lungs.

The third case showed great development of fat on the upper arms, and especially on the abdomen, where the fat lay in great folds or tumors. She was somewhat deaf, apathetic, and had headache. This case also came to autopsy. The thyroid gland was larger than normal and somewhat calcified, but nothing else of moment was found. Dr. Dercum says that the nodules of soft tissue are at first deposited in one location, or, perhaps, in corresponding places on the upper or lower extremities. Then other parts are attacked, though some portions of the body are left without much fat development, and soon pain and other nervous symptoms appear. In the first of these cases of adiposis dolorosa the thenar and hypothenar groups of muscles showed the reaction of degeneration. Electrical changes are never present in acromegaly. Also the absence of any marked enlargement of the hands, feet, and face, as well as no bone-growth, excludes confusion with acromegaly.

Prognosis.—Marie estimates the duration of this disease to be from ten to twenty years. Of twenty-five cases giving the estimated duration only three have died, but the average duration of the disease in the twenty-two living cases is twelve and one-half years.

Fifteen of the twenty-five cases are over ten years in duration, and six over twenty years, while the range is from three years to thirty-four years (Bury's, and Graham's second case, both dead).

This disease is one of continuous progression, especially in the growth of the bones. Under treatment, or without treatment, periods of apparent quiescence, or periods of cessation of symptoms occur, and the soft parts of the hypertrophied portions of the body not only may not enlarge but actually appear diminished in size. Yet even in such cases the bones continue to grow.

These periods, when the patient may say he feels well, are, sooner or later, followed by marked exacerbations of all the symptoms, often coming on suddenly, even precipitately. These symptoms, all of which may be ameliorated by treatment, are severe headache, often dizziness, great constipation, troublesome dyspepsia, aggravated eye or ear symptoms, great temporary loss of strength, and melancholia, with more or less pain referred to various parts of the body. At this time the soft parts on the hypertrophied portions of the body appear larger, although œdema cannot be found.

A more or less complete recovery from these exacerbations, or severe symptoms, generally occurs, but the patient is not quite as well in all respects as he was before. Thus the disease proceeds, with some symptoms more or less constant, until there is hardly a tissue or organ of the body that is not affected in greater or less degree.

Finally, little by little, the patient falls into a condition of progressive cachexia, with partial or nearly complete loss of muscular power, due to atrophy of the muscles, so that he may be compelled to remain in bed. This condition may last for several years, and then death occurs unexpectedly, with the appearance of syncope. It

is possible that an enlarged pituitary body may cause coma and death. Most cases of acromegaly, however, die of some intercurrent affection.

The headache may become so severe as to cause suicidal tendencies, and temporary insanity may occur, probably caused by pressure from an enlarged pituitary body.

TREATMENT.—This disease is incurable, but in any given case we can safely expect to ameliorate many of the nervous symptoms. Of all treatment rest is the most important, under which all the phenomena, except those produced by actual lesions, will improve. Pain, the most frequent cause of complaint, has been treated by antipyrine, acetanilide, phenacetin, exalgine, caffeine, and codeia. Dulles gave salol and phenacetin for the headache, while in Ruttle's case it was helped by exalgine in three-grain doses every eight hours. Phenacetin, occasionally, and codeia, in small doses, continued for one or two weeks, have given good results in the writer's case.

The constipation should be treated, while dyspepsia, when present, can be best helped by a diet that requires but little mastication, as prognathism, which is so frequently present, is generally the cause of the dyspepsia. The bromide of potassium is often of service in relieving the headache and the feeling of pressure in the head.

Positive impairment of sight or hearing cannot be improved, and if the sight is affected at all the loss of vision will probably increase. Tinnitus aurium, if due to this disease, can probably be but little, if at all, helped.

Arsenic in some form, given for a long time, has done good service. Denti used the arseniate of iron. Mosler used baths and the faradic current to the back.

But, as before stated, any tonic or bracing treatment, combined with rest, will generally cause a cessation of the acute symptoms and a pause in the disease, except in the last stages. A theoretically good treatment, owing to the condition of the blood-vessels, dilated and with weakened walls, and of practical value in Mosler's and the writer's cases, is ergot. Ergot or ergotine should be given continuously for a long period, the exact length of time being governed by the results.

If there is atrophy of the muscles and great loss of muscular power strychnia, by the mouth or hypodermically, is of value.

Phosphorus has been used in acromegaly, also the Oertel treatment, and the milk diet.

Where glycosuria has been present the diabetic diet has been used.

Oliver T. Osborne.

ADIPOSIS DOLOROSA. At a meeting of the American Neurological Association, held in New York in June, 1892, the writer presented the histories and photographs of three cases of an affection which up to that time had not been recognized. The first of these cases had been under the writer's care since 1887, and is still living. The second and third were discovered in the wards of the Philadelphia Hospital in 1891, and both cases dying, autopsies were held in each instance.

The histories of these cases are briefly as follows:

Case I.—M. G——, aged fifty-one, female, widow, a native of Ireland, and a domestic. Her father had died at forty-five of erysipelas. Her mother, who had had eighteen children, died at forty of some affection incident to the menopause. Of her brothers and sisters, seven died in childhood, one in adult life of pleurisy, one sister in childbirth, a brother and two sisters of phthisis, while the remaining five are living and apparently in good health. None of the patient's relatives have ever suffered, as far as she knew, from symptoms similar to her own, nor had any of them ever had any nervous or mental affection.

As a child she had had measles, whooping-cough, and scarlet fever. Menstruation began normally at fifteen. At eighteen she married. Some years later she had an attack of pneumonia but made a good recovery. She had in all seven children and one miscarriage. Five children died in early childhood, one from cholera infantum, two from measles, one from "congestion of the brain," and the fifth from spasms. The menopause set in abruptly at thirty-five. From this time up to within two or three years her health had continued good. She had undergone some increase in weight, but beyond this nothing worthy of mention could be elicited. Syphilis was denied, as was also alcoholic excess. However, the condition of the patient on several occasions upon her return to the hospital after furlough was such as to throw more than doubt upon her denial of alcoholic abuse.

When forty-eight or forty-nine years of age she noticed that her arms were becoming very large. The upper arms and shoulders appeared swollen. The swelling continued steadily to increase and was for about a year unattended by any other symptom.

In November, 1886, she was admitted to the surgical wards of the Philadelphia Hospital for the rupture of a varicose vein of the leg. In the following February she was transferred to the medical wards for a severe attack of bronchitis. Later she had an attack of severe pain and swelling in the right knee, attended by chill and fever. She was treated for rheumatism and promptly relieved. Two weeks after this she complained of a sharp darting pain in the right arm. It begun on the outer aspect above the elbow and gradually increased in severity and extent, spreading upward to the shoulder and neck, and downward to the forearm and hand. It was shooting and burning in character. She felt at times as though hot water were being poured upon the arm, and again as though the hands and fingers were being torn apart. No rise in temperature was noted. The pain was often paroxysmal, but it was never absent. On June 4, 1887, she was transferred to the nervous wards of the hospital and came under the care of the writer.

Her appearance at this time was striking. She was a tall, large-framed woman who looked as though she had at one time presented a fine physical development, but she seemed unnaturally broad across the back and shoulders. On removing the clothing an enormous enlargement of these parts was disclosed. The enlargement affected both shoulders, the arms, the back and the sides of the chest. It was most marked in the upper arms and back, forming here huge and somewhat pendulous masses. It was elastic and yet comparatively firm to the touch, and it was impossible to produce pitting. In some situations it felt as though finely lobulated, and in others, especially on the insides of the arms, as though the flesh were filled with bundles of worms.

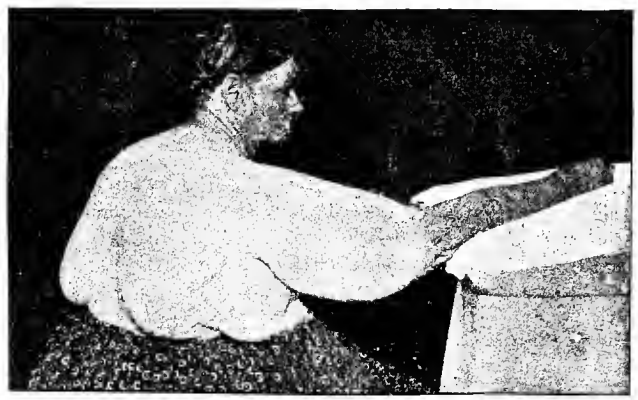

Fig. 4.—Author's First Case, Showing Large Masses of Fat on Back and Upper Arm.

The skin was not thickened; it did not take part in the swelling, and it was not adherent to the subjacent tissues.

In addition the swelling was very painful to pressure. Pronounced pressure appeared to be absolutely unbearable. The nerve-trunks also were exquisitely sensitive, but this painful condition was not by any means limited to them, but permeated the swollen tissue as a whole.

The muscles were not involved in the swelling. The affected parts were, however, quite weak. Examined electrically the muscles of the shoulders and arms yielded a negative result, partly because of the great resistance caused by the intervening tissue. Slight qualitative and quantitative changes were noted in the muscles of the forearms, while in the hands distinct reaction of degeneration was noted in the thenar and hypothenar groups, more evident on the right side.

Cutaneous sensibility was much diminished. On the right arm various areas existed in which no response whatever was given to the æsthesiometer. They were large and irregular in shape, and very sharply defined, and were present on both the inner and outer aspects. In the finger-tips the points could not be at all separated. In the left arm, some impairment of sensation was detected on the outer aspect of the forearm, and in the finger-tips sensation was decidedly below normal. Sensibility to heat and cold appeared also to have been lessened.

On examining the legs it was found that cutaneous sensibility was distinctly lessened on the right, while showing little or no impairment on the left.

No enlargement was noted at this time in any part of the body save in the arms and shoulders. The face was pale, as were also the mucous membranes. There was, however, a little color in the cheeks, more noticeable at times. Her features were well formed and intelligent. Her hair was dark and fine. Her mind was unimpaired, except that at times she was much abstracted. Sometimes she gave conflicting answers to questions, so that the latter had often to be repeated.

Ten days after her admission to the nervous wards she had a chill, followed by fever and a painful herpetic eruption over the upper portion of the left arm, and anterior portion of the left side of the chest. Some five or six days later another crop of vesicles made its appearance on the back and on the front of the chest.

Nothing further worthy of note occurred until October 13th, when the patient had another severe attack of bronchitis, which was accompanied by much dyspnœa.

Fig. 5.—Another View of Author's First Case.

In the latter part of the following December it was noted that during one of her paroxysms of pain the swelling of the right arm became more decidedly lobulated. The arm became more sensitive than ever, and on examination hard, cake-like masses were felt, resembling, as the resident physician expressed it, the caking of milk in a breast. This caking or increased lobulated feel was subsequently repeatedly noticed during paroxysms of pain. At this time also she suffered from an attack of pain in the right knee, and in the popliteal space a diffused swelling was felt which exhibited the same nodulated feel as did the swelling elsewhere. It was also very painful.

At various times subsequently paroxysms recurred, during one of which swelling was noticed in the posterior triangles of the neck. The latter seemed later to be permanently fuller than normal. Bronchitis also recurred, accompanied by dyspnœa, and at one time with free expectoration of bloody mucus.

In the following April she experienced an attack of pain of unusual severity. The latter, which involved the right arm and shoulder, right side of trunk and back of neck, now for the first time spread to the face and head. The right side of the face became distinctly swollen, and presented to the touch the same nodulated feel so characteristic of the swelling in other portions. At the same time the tongue and pharyngeal tissues appeared to become swollen. Her tongue, she said, felt much too large for her mouth. In addition her voice was very hoarse, and she spoke with great difficulty. This condition persisted for upward of a week, and then slowly subsided. For some time, subsequently, she spat blood, the source of which was not determined, though it appeared to come from the throat. The reddish color in the cheeks also became more pronounced, until it covered the entire forehead like an intense blush. This blush was afterward observed to occur with other paroxysms of pain.

During the summer of 1888 the patient's condition underwent some change. The paroxysms became less frequent and less severe. Hand in hand with this improvement, sweating became much more marked. However, paroxysms occurred from time to time, and upon one occasion a thick welt-like swelling, exquisitely painful, was observed extending from the upper and inner angle of the scapula, perpendicularly down the back to very nearly the lumbar region. Upon another occasion swelling again made its appearance in the right popliteal space, as well as on the inner aspect of the knee. In the latter locality the swelling became permanent, and the tissues presented the same peculiarities as noted elsewhere. Pain also occasionally appeared in the left arm. Prolonged attacks of cardiac dyspnœa occurred every week or two, and apparently independently of bronchitis.

An examination of the eyes by Dr. de Schweinitz revealed contraction of the fields of vision for form and colors, most marked in the left eye. The other special senses, hearing, taste, and smell, appeared to be somewhat obliterated. An analysis of the urine yielded a negative result. A blood-count failed to reveal an increase of white blood-corpuscles.

Upon a number of occasions the patient during paroxysms of pain vomited blood; upon several occasions this was observed by the writer himself. The quantity could not be accurately estimated, but while it was never large at a single emesis it was constantly brought up in repeated vomiting during an entire night or day.

Measurements were made of this patient at various times, and these have shown a steady increase in the bulk of the enlarged parts.

Of late the patient has not suffered as intense pain as formerly. Cardiac dyspnœa, however, is a frequent and distressing symptom. The face is still flushed. Recently, shooting pains have appeared in the abdominal region, and examination discloses in this region an extensive deposit of tissue to which the pain is referred. A large longitudinal wheal, especially sensitive, is found in the left lumbar region.

Swelling has also made its appearance over the left hip, and to some extent over the right. The thighs and buttocks do not seem enlarged in proportion, but soft masses are now found on the inner sides of both knees, the right larger than the left, the former more painful to pressure. A small nodule to the right of the scrobiculus is especially painful.

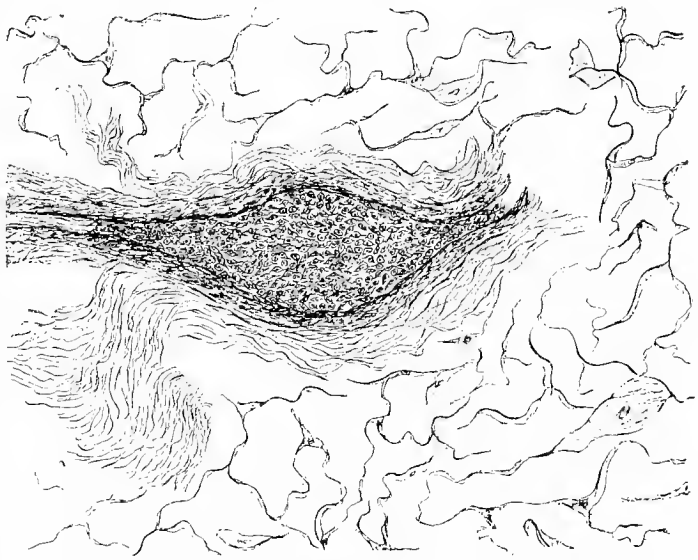

Fig. 6.—Microscopic Drawing from Portion Excised from Left Arm, Middle Third, Showing Embryonal Connective-tissue Cells (Carmine). (Drawn by Allen J. Smith.)

At various times, by means of a Duchenne trocar, fragments for microscopic examination were removed from either arm. They revealed connective tissue and fat-cells present in varying degree. It was observed that the former was decidedly embryonal in type, the

cells being large and fusiform, and their nuclei correspondingly large and prominent. The fat-cells for the most part were associated with these connective tissue-cells, and occasionally individual fat-cells were seen in which the fatty metamorphosis had not been complete. These appearances are well illustrated by Figs. 6 and 7.

In one of the fragments removed the writer was fortunate enough to find nerve-elements. These had

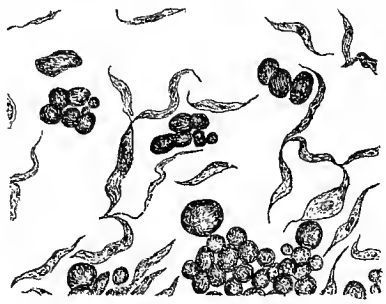

FIG. 7.—Another Portion of the same Specimen, Showing Fat Cells and Oil Drops. (Drawn by Allen J. Smith.)

probably been included in the grasp of the trocar by the latter grazing a blood-vessel, as the fibres were non-medullated. The latter revealed decided changes, their connective tissue was denser than normal, and they presented an unusual number of nuclei, which here and there were aggregated in clusters (see Fig. 8). The most interesting finding, however, was a more or less complete ganglion of relatively large size (see Fig. 6). The capsule of the ganglion was evidently sclerosed. Certainly it appeared very dense and excessively thick.

CASE II.—E. W——, female, aged sixty-four, married, a native of England. Her father had died of alcoholism at middle life; her mother of œdema of the brain (verified post mortem). Has living an elder brother and sister, and one younger brother. The younger brother, when a child, was peculiar, he would run to people in a fright and say that he was drowning, and the like. He is now in average health, but drinks heavily. He has a contracture of the ring finger. Has nine children, all of whom appear to be well. The older brother suffers periodically from violent headache; also, since a young man, he has suffered from constantly cold feet, this so severe as to disturb sleep, and cause great distress. He has had five sons and two daughters. One son died of tetanus (traumatic), the others are well. One daughter has a contracted middle finger of the right hand; has never suffered pain in the finger. Patient's sister is living, sixty-five years old; no children.

The patient herself does not remember having had the ordinary diseases of childhood. In early infancy she had convulsions, which recurred with great frequency for a time. On her being relieved of lumbricoid worms, however, the convulsions ceased.

At seventeen she was married. She had two sons, the older of whom is now forty, and who has seven healthy children. The younger son died at two years of age, of hemorrhagic diarrhœa. The patient had no miscarriages and no still-births. Left her husband because of venereal disease, contracted by the latter. She was told by a doctor that she had escaped infection. A year later, however, she had sore throat, with white patches. For many years she was an immoderate drinker. For weeks at a time she was intoxicated every night.

Menstruation began at eleven and ceased abruptly at thirty-five. She lost habitually an unusual quantity of blood, but never suffered any discomfort.

Her present malady began about fifteen years ago, when she was forty-nine years old. At that time she was living in California. The first thing noticed was a constant feeling of coldness about the knees, followed by swelling, which gradually increased. At first she thought that the swelling was due to her growing fat, but later was astonished to see that there was a localized mass on the inner aspect of each knee. At the time there was dull aching pain in the affected parts. Later, the right arm became involved, a mass making its appearance on the outer aspect. Her body she now noticed also became larger, as her stays were too small for her. During this time, while still in California, inability to perspire freely, except at the Turkish bath, was marked, and was part of her reason for coming East. Since she has been in Philadelphia the lack of perspiration has not been as marked as before. Various plans of treatment were tried, but did not influence the progress of the disease, *i.e.*, the growth of the swelling. Five or six years ago, injections of chloroform were made into the swellings on the inner sides of the knees, but no good was accomplished. Painful ulcerations were the result, and scars of considerable size mark their location.

About five years ago a slight swelling appeared in the epigastrium. This gradually increased in size until it resembled the breasts in shape, and afterward spread so as to involve nearly the whole abdomen.

From the knees the process extended to the thighs, and gave rise to large masses on their outer side and about the hips.

At various times she had suffered with pains apparently situated in the enlarged tissues, or running down the limbs. Sometimes these attacks were fairly well localized in one limb, in one side, or about a joint.

Five years ago her attention was called to a peculiar condition of the right hand. The last phalanx of the second finger began to be fixed in a flexed position, while the end of the finger appeared to be growing somewhat smaller. Later the remaining fingers of this hand became involved, and all the phalanges deformed. The deformity, as seen now, is flexion of the first phalanx, marked over-extension of the second, and half-flexion of the third. The thumb is also stiff, but all of its joints are flexed. For some time she has noticed the thumb of the left hand becoming like that of the right.

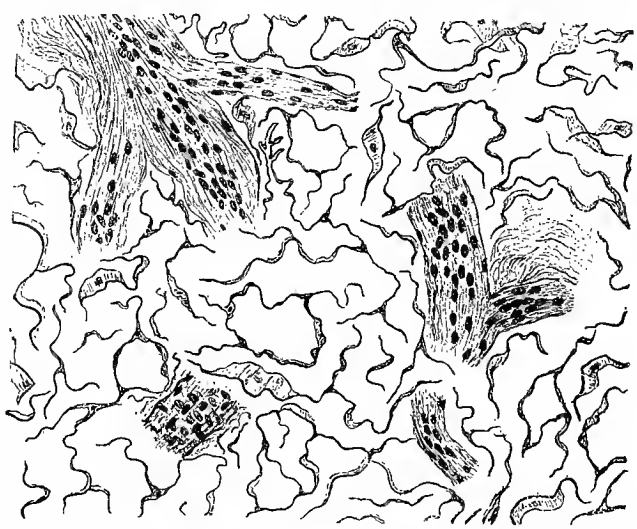

FIG. 8.—Microscopic Drawing from Portion Excised from Left Arm, Lower Third, Showing Inflammation of Non-medullated Nerves (Carmine). (Drawn by Allen J. Smith.)

A year ago the patient had a quasi-rheumatic attack affecting the deformed hand and the arm. The pains seemed to run up and down in the arm rather than about

the joints. Some months ago she had pneumonia of the right lung, and made a good recovery.

For several months past she has had slight uterine hemorrhages at times, associated with which were dull,

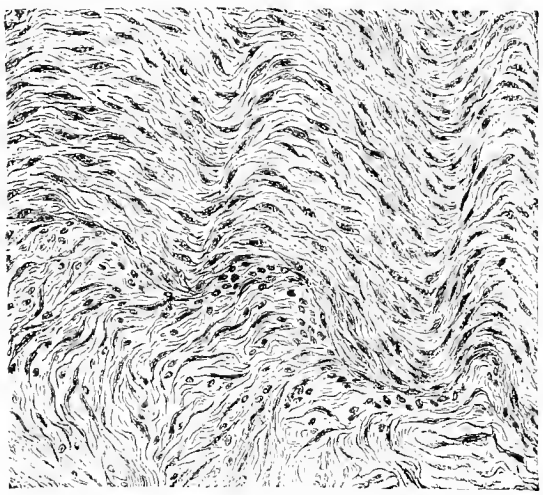

FIG. 9.—Another View from the Same Portion of Tissue Removed from the Left Arm. (Drawn by Allen J. Smith.)

aching pains, resembling those formerly felt before menstruation.

In addition, she stated that the swelling had spread up from the knees over the thighs unequally; that the left thigh and buttock had been earlier and more conspicuously enlarged than the corresponding parts on the right side. Gradually, however, the latter became enlarged to an almost equal degree. Later, swelling appeared over the left arm, and later still on the back and sides of the trunk, and wherever appearing, it gradually became diffused, and finally reached very great proportions. The patient further volunteered the statement that she had formerly been very slight in build.

To ordinary observation she merely presented the ap-

FIG. 10.—Author's Second Case.

pearance of an excessively obese person. However, examination soon revealed that the enlarged tissue was very unevenly distributed. In the region of the knees, where it had first made its appearance, it was excessively irregular and lumpy. To the fingers it resembled in a remarkable degree the swollen tissues of Case I. It gave the same nodular feel, and could not be made to pit on pressure. At the time of the examination no tenderness existed in the swellings, but shooting pains were referred to them in various situations. This was particularly the case in the mass over the right hypochondrium. In addition, she complained of scalding sensations on the inside of the right cheek and the right side of the tongue. Nothing abnormal could be discovered in the mucous membrane of these parts. No tenderness could be discovered in any of the nerve-trunks at the time of the examination. The patient was excessively weak, and could move about her bed or sit up only with great difficulty. Her grip was almost *nil*. No tendon-jerks could be elicited, probably because of purely mechanical difficulties. For the same reason an electrical examination could not be made.

Slight diminution of tactile sensibility and of the temperature sense and also some analgesia were present. An area of absolute anæsthesia existed on the back of the left arm, extending thence over the posterior aspect of the left shoulder. A marked increase in the swelling had taken place during the last year, measurements showing, for instance, that the left forearm had increased one inch and seven-eighths, and the right forearm one inch and three-eighths; the left arm one and a half, and the right arm two inches. This increase appeared to be maintained throughout.

FIG. 11.—Rear View of Author's Second Case.

Subjectively the patient complained much of headache. Her face was very much flushed, and she suffered greatly from cardiac dyspnœa. It was a persistent and distressing symptom. Examination of the eyes proved negative, as did also that of the urine. Perspiration, according to the patient's statement, was scant. Face not involved in the enlargement; no subnormal temperature; hair thin, but not excessively so; no difficulty in speech; no mental impairment.

The patient remained very much in the same condition for some two weeks following her admission to the nervous wards, when her dyspnœa greatly increased. Her pulse, already soft and compressible, became irregular and intermittent. This condition, though relieved from time to time, persisted until hands and feet became puffy, the face cyanotic, and the lungs œdematous and congested. Death occurred on December 22, 1891.

Autopsy, December 23d.—Body that of a very large woman. Weight estimated at about three hundred pounds. Face dark from venous congestion. Some discoloration on under surface of body and thighs. A number of large white scars on either side over the knees. Legs and feet œdematous. Body distorted and flattened, as though by its own weight.

Scalp and calvarium revealed nothing abnormal. Veins of dura and longitudinal sinus full. Venous congestion of the pia. Cortex a little darker than normal. Puncta vasculosa prominent. Brain otherwise normal. Spinal cord appeared normal. Skin of thorax appears normal. The subcutaneous tissue is fatty and moist.

Thyroid gland small, indurated, and infiltrated by calcareous matter in both lobes.

Right lung œdematous and tightly adherent to chest-wall. Left lung œdematous, with hypostatic congestion posteriorly. Both pleural cavities contain a large excess of fluid.

Pericardium contained some six or eight ounces of fluid, in which was suspended some flocculent lymph. Weight of heart twenty-seven ounces; the right side dilated, the moderator band much thickened. Walls of left side also much thickened, marked hypertrophy of the columnæ carneæ and papillary muscles. Some fatty change, especially in the walls of the right ventricle.

Over the abdomen the subcutaneous fatty tissue was three inches thick. About a pint of ascitic fluid in abdomen. Stomach much dilated. Intestines normal. Liver showed some fatty infiltration; otherwise normal. Spleen apparently normal, though somewhat dark. Kidneys both reveal, excepting slight adhesion of the capsules, nothing specially abnormal.

In the pelvis an ovarian cyst, containing some six ounces, and a hydrosalpinx were found on the left side. Uterus seemed a trifle larger than normal. Bladder normal.

Brain, cord, some of the nerve-trunks, pieces of skin and subcutaneous tissue, pieces of the liver, kidneys, spleen, a fragment of muscle, and the whole of the thyroid gland, were removed for microscopic examination. The specimens were left in the care of Dr. H. W. Cattell, assistant to the pathologist of the hospital. Unfortunately, Dr. Cattell fell ill with scarlet fever, and during his absence the specimens, together with those of Case III., were thrown away by an attendant.

Case III.—M. M——, aged sixty years, widow, a tailoress by occupation, and a native of Germany, but a resident of America for twenty-six years, was admitted to the nervous wards of the Philadelphia Hospital, October 7, 1891. Memory very poor. History obtained in part from relatives.

Her father and mother healthy, though her mother died of heart disease. She had seven brothers and sisters, all apparently well. She had no children; had never been pregnant.

Many years ago a lump appeared at the back of the neck, for which she consulted Dr. Gross at the Jefferson Medical College, but for some reason no operation was performed. At various times thereafter swellings made their appearance in various situations. Further, she lost more blood at her menstrual periods than normal. Occasionally she suffered from hæmatemesis and epistaxis.

Fig. 12.—Author's Third Case.

The climacteric occurred at forty-six. No history of any intercurrent affections. Mental impairment had been noticed for about two years.

On examination the patient was found to be excessively feeble. For some two weeks she had been unable to walk. She lay, for the most part, in a quiet, apathetic state, though when aroused she answered questions slowly, but intelligently. She was also somewhat deaf.

Examination further revealed, soft, fat-like masses or swellings in various situations. Thus, a large, soft mass was found over either biceps, and others, somewhat smaller, over the outer and posterior aspect of either upper arm. Two large masses were found over the belly, separated above the umbilicus by a deep, transverse crease. Another gave excessive prominence to the mons Veneris. From the back of the neck, at its lower part, sprang a big mass like a hump, while a diffuse swelling gave a

Fig. 13.—Rear View of Author's Third Case.

cushion-like coating to either half of the back, and extensive deposits gave unnatural prominence to either hip. In marked contrast, the deposit was absent from the forearms and hands, from the face, from the thighs and legs, and from the buttocks. The gluteal regions, in fact, seemed flattened and sloping.

The deposit over the back seemed tolerably firm and resistant; over other portions it was quite soft, though elastic, and exhibited the same nodular feel noted in the previous cases. Further, it was discovered at once that these masses were painful to the touch, the patient complaining very much when only moderate pressure was exercised. This was especially true of the deposits over the arms and back of the neck. In addition, the patient complained of stabbing pains in the deposits, more marked in the regions just mentioned. There was no tenderness over the nerve-trunks. She complained also of headache.

In making the examination it was also further noted that the left radius was rough and nodular for about two and a half inches in its middle third; also, that there was a large discolored area on the outer aspect of the left forearm resembling a syphilitic scar. Both tibiæ were somewhat nodular, though no scars were discovered on the legs. A few white scars were seen on the forehead. Finally, quite a number of purpuric spots were observed on the forearms, thighs, legs, and back.

The skin of the forearms and hands, and that of the legs and feet to a less extent, was dry, dark, and much roughened.

Cutaneous sensibility was found generally diminished, while a few patches of anæsthesia were noted. One of these was an area diffused over the right side of the trunk and the right shoulder. They appeared to be constant, and were confirmed at various examinations.

Owing to the extreme weakness of the patient, the study of the eyes could not be made satisfactorily, but, as far as it went, was negative. The urine contained albumin, though no casts were found.

In answer to questions the patient said that she had not been sweating freely for years, but owing to her mental condition no importance was given to this statement. She at no time presented any change in temperature. Her hair was well preserved.

The patient seemed to fail slowly and steadily, although liberal diet and stimulants were freely used. Her dementia gradually deepened, and for some days before death she voided urine and fæces involuntarily. She finally died in a comatose state on November 5, 1891.

Autopsy, November 6th.—Body that of a large woman with irregularly distributed fat-like masses. Some discolorations on the back. Small bed-sores beginning on the buttocks.

Scalp and calvarium normal. Dura normal. Pia very œdematous. Brain very soft and œdematous. Cord revealed nothing abnormal.

On incising the skin of the chest and abdomen it was found to be normal in appearance, but the subcutaneous tissue, which looked like very white fat, was excessively thick, attaining below the umbilicus a depth of seven inches.

The thyroid gland was larger than normal, harder to the feel, and much calcified, especially the right lobe.

The heart weighed eight and a half ounces. Both aortic and mitral valves were slightly thickened. Heart substance evidently fatty. Lungs emphysematous.

The mucous membrane of the stomach revealed a chronic gastritis. The liver weighed forty-four ounces, and, beyond some fatty infiltration, was practically normal. Spleen normal. The kidneys, however, showed decided shrinking and loss of cortical substance, with somewhat adherent capsules. Nothing noteworthy was seen in the pelvic organs.

As in Case II., brain, cord, nerve-trunks, skin and subcutaneous tissue, thyroid gland, and portions of other viscera were removed for microscopic examination, but, as already mentioned, the specimens were subsequently lost.

It was not without some hesitation that these cases were presented together. The writer was well aware that without a microscopic examination to supplement the autopsies their study was incomplete, and yet the cases are in themselves so interesting, and appear to be so unusual, that their publication in a group, with such data as are at hand, was more than warranted. Case I. had originally been published in the *University Medical Magazine* for December, 1888, under the title, "A Subcutaneous Connective Tissue Dystrophy of the Arms and Back, Associated with Symptoms Resembling Myxœdema." Case II. had been discovered in the medical wards of the Philadelphia Hospital by Dr. Frederick P. Henry, in 1890, and was published by him in the *Journal of Nervous and Mental Diseases* for March, 1891, as a "Case of Myxœdematoid Dystrophy." Dr. Henry fully recognized the relation existing between this case and that previously described by the writer, and he adopted the term dystrophy in order to bring the cases "into the same category." In November, 1891, this case (Case II.) having been transferred to the nervous wards of the Philadelphia Hospital, came under the care of the writer, and was studied again. The account here given is abstracted partly from the notes of Dr. Henry, and partly from those of the writer.

Case III. was discovered in the nervous wards in October, 1891.

Certainly these cases differ radically from ordinary cases of lipomatosis, and certainly the nervous symptoms present must have a special significance. To begin, the enlarged tissue makes its appearance in a very irregular way. Nodules of soft tissue are, at first, deposited in some one situation, or perhaps in corresponding places in both arms or in both legs. For a time the deposit is limited to these original areas, but subsequently it makes its appearance elsewhere, and may become very extensive. Regions, however, may exist which remain permanently uninvaded. In Case I. the enlargement was first noticed in both upper arms, and later in the back. Subsequently a swelling made its appearance on the inner aspect of the right knee, to be followed months after by a similar swelling in a corresponding position over the left knee. Later still, swellings made their appearance in various other situations. However, the legs, with the exception of the knees, have remained free from involvement, while the thighs and buttocks have only recently shown a doubtful change. In Case II. the enlargement began on the inner aspect of either knee, and then gradually spread unequally over the thighs and buttocks. Later, the left arm became involved; next the sides and back, and, finally, the entire trunk. In Case III. the enlargement began in the back of the neck, and then at various times appeared in other situations. It remained absent from the face, the forearms, the legs, the thighs, and the buttocks. It is a peculiarity of this case, also, that the enlargement tended to produce distinct segregated masses.

Not only is the development of the enlargement irregular and even capricious in these cases, but there is, in addition, another important fact to be remembered, and that is: that at some time or other the enlargement is accompanied by pain or other nervous symptom. Thus in Case II. pain, shooting in character, and a sensation of coldness preceded the appearance of the nodules on the insides of the knees. In Case I. shooting and burning pains made their appearance about a year after the swelling had appeared in the arms, while similar pains, very great in intensity, preceded the appearance of the swelling on the inner aspect of right knee and in other situations. Case I., it should be remembered, was observed by the writer for a number of years, and was therefore studied in great detail, and pain was noted as a marked feature of the case, especially in the early course of the disease. Occasionally it was observed in old areas of enlargement, and again in regions free from the swelling, but in which the latter subsequently appeared. In Case III. stabbing pains were complained of and were referred to the deposits, and the latter were very painful to examination.

We may say, therefore, that pains, shooting, burning, or stabbing in character, were present in all cases at various times in their history.

Some of the paroxysms observed in Case I. were particularly suggestive. Sometimes a welt-like swelling suddenly made its appearance, evidently following the course of a cutaneous nerve-trunk and at the same time being exquisitely painful. After a time the swelling would become slightly less, but would never wholly disappear. Several such "welts" are still demonstrable in Case I. If the paroxysm of pain made its appearance in an area of old enlargement, that is, reappeared or recurred, a decided and sudden increase would take part in the swelling; and it would become for the time being firmer and more resistant and occasionally more nodulated than before, and generally a permanent increase in the swelling could be demonstrated. Further, it should be remembered that at one time some of the nerve-trunks of the right arm were very sensitive to pressure, that some of the muscles, those of the thenar and hypothenar groups of either hand, revealed reaction of degeneration, and finally that the patient suffered on two occasions from herpes zoster.

In Cases II. and III. tenderness over the nerve-trunks was not present at the time of the examination. In Case I., however, this symptom is also no longer present, its absence having been noted for some time past. This and other circumstances justify the assumption that Cases II. and III. were further advanced than Case I., and that the latter was really observed during a developmental period and while more active changes were going on.

Among the nervous symptoms must also be placed the diminished cutaneous sensibility and the patches of anæsthesia as well as perhaps the excessive weakness. It is probable also that the absence and the diminution of sweating belong to this category. It will be remembered that this symptom was undoubtedly present in Cases I. and II. and doubtfully in Case III. Lastly, headache was noted in all the cases.

Among other symptoms present in these cases should be noted hæmatemesis in Case I., hæmatemesis and epistaxis in Case III., and a recurrence of uterine flow many years after the cessation of menstruation in Case II. In Cases I. and II. the menopause occurred unusually early, namely, at thirty-five, and in Case II. menstruation was unusually free. In Case III. the menopause occurred at forty-six, and menstruation was likewise said to have been excessive. Finally Case III. presented a well-marked purpura. What significance these symptoms may have, it is impossible to say. It may not, however, be out of place to recall the not infrequent occurrence of uterine hemorrhages in women who subsequently suffer from myxœdema.

Bronchitis is a most frequent and persistent symptom in Case I., while both Case I. and Case II. suffered mark-

edly from cardiac dyspnœa. But these symptoms were absent in Case III.

As already stated, fragments of the enlarged tissue were removed from Case I. by the Duchenne trocar, as also from Case II. In both instances fat-cells and connective tissue were found in varying proportions. At times the connective tissue appeared decidedly embryonal in type (see Fig. 4). This was especially so in Case I., in the fragments removed from the upper third of the right arm. It would seem further that in the more recent formations the fat-cells are less perfectly developed, while in the older areas a fully formed adult fatty tissue is present. It is especially to be regretted that the loss of the specimens from the autopsies of Cases II. and III. prevented a confirmation of these results.

The fact that in both cases the thyroid gland was found indurated and much infiltrated by calcareous deposit is not only very interesting but exceedingly suggestive. Without microscopic studies, however, and without a more extended series of cases it is impossible to draw a conclusion. The part, if any, played by the thyroid in this curious affection can only be determined by future autopsies. It goes without saying, also, that the thyroid should be studied in every case of obesity, whether typical or otherwise, that reaches the post-mortem table.

With the above data before us, it is impossible to classify these cases under any well-established disease. Evidently the affection is not simple obesity. If so, how are we to dispose of the nervous elements present? It is equally certain that we have not myxœdema to deal with. All of these cases lack the peculiar physiognomy, the spade-like hands, the infiltrated skin, the peculiar slowing of speech, and the host of other symptoms found in myxœdema. It would seem, then, that we have here to deal with a connective-tissue dystrophy, a fatty metamorphosis of various stages of completeness, occurring in separate regions, or at best unevenly distributed and associated with symptoms suggestive of an irregular and fugitive irritation of the nerve-trunks—possibly a neuritis. This, however, does not embrace the whole truth, and it remains for future research to determine to what this neuritis is due, whether it is a cause of the fatty metamorphosis or only concomitant, and whether the thyroid gland does not play some mysterious part in its causation.

Inasmuch as fatty swelling and pain are the two most prominent features of the disease, the writer has proposed for it the name *Adiposis* Dolorosa.*

F. X. Dercum.

ÆTIOLOGY (now often less authoritatively written Etiology; from Lat., *ætiologia;* Gr., **αιτία**, cause, **λόγος**, discourse) is the general science of causation. In a narrower sense it forms one of the grand divisions of Biology—the science of living things—the others being Morphology, Physiology, and Distribution. Ætiology deals with the causes and the explanations of the phenomena of biology, and with the whole subject of origins. Darwin's classical work, the "Origin of Species," is a good example of a monograph in ætiology. Examples in medical literature will occur to everyone. Professor Huxley has defined ætiology in biology as that science which has for its object "the explanation of biological phenomena by showing that they constitute particular cases of general physical laws."

If we keep this definition in mind we shall immediately discover the place of ætiology among the medical sciences. The phenomena of disease are quite as truly biological phenomena as are those of health, for pathology is simply the morphology, physiology, and ætiology of the morbid organism. In this case, therefore, ætiology has for its special province *the explanation of the phenomena of disease by showing that they constitute particular cases of general physical laws.* The importance of a science which seeks to do this can be appreciated only by those familiar with the history of medicine from the time of its gradual emancipation from priestcraft and dæmonism, through the humoral pathology, methodism, pneumatism, and the like, to the dawn of the cellular pathology in the middle of the present century. It means nothing less than the search of modern science for the causes of disease.

The word ætiology is used in the medical sciences in two distinct senses, which may be described as the proximate and the ultimate, or the practical and the theoretical. The term is known most widely in connection with the proximate causation of diseases, and to observe the difference in its application it is only necessary to take an example from any well-known disease, for instance, typhoid fever. By the ætiology of this disease is usually meant the mechanism of infection; how the specific germ (if this be now allowed to exist) is distributed in a community, how it finally arrives in the alimentary canal and by what vehicles, namely, polluted milk, water, or other food materials, secondary infection, climatic or "pythogenic" influences, broken drains, miasmata, the level of the local ground-water, etc. This aspect of the subject may be called the proximate, immediate, or practical side of ætiology. But after the specific *materies morbi* of typhoid fever has arrived in the body it has still to do its work. It must somehow derange the normal structure or function, or both, of some part or parts, or of the whole body. It must unduly disturb the living stuff. It is the doing of this act which constitutes true ætiology; this is the real causation of typhoid fever. The ætiology of the disease is the ultimate action upon the normal organism, the reaction to which is seen in the chain of phenomena called the disease. Obviously, practical ætiology becomes the foundation-stone of sanitary science and preventive medicine; while theoretical ætiology is the goal of pathology.

We may conceive of the living organism as a living machine, having, in health, certain normal structure and functions. Disease will then be manifested by abnormal structure or function. This might be due, conceivably, to inherent defects in the constitution or construction of the machine,—as when a watch breaks down or keeps time badly owing to poor construction or poor constituent materials; or to some interference with the machine by something proceeding from without,—as when dirt or injury interferes with the running of the watch. Diseases due to defective structure or poor materials of the machine may be called *intrinsic*, diseases coming from the environment may be called *extrinsic*. The former are strictly constitutional, the latter strictly environmental in their origin. But organisms can never be free from the influence of their environment to which they must constantly be adjusting and readjusting themselves. So fundamental is this phenomenon that Mr. Herbert Spencer has seized upon it as the main phenomenon of life itself, which he defines as "the continuous adjustment of internal to external relations;" or, in other words, adjustment of a changing organism to its changing environment. There can be no question that for the student of ætiology this is the most important feature of normal life, and that it furnishes a sound basis for his definition of disease. From this point of view life is a long series of departures from the normal, each followed by a return or readjustment. Adopting the definition and applying it to disease (abnormal life) we may define the latter as *partial failure in the adjustment of internal to external relations*—a total failure being death, either local or general.

Physiology teaches that the function of functions is metabolism, and the continuous adjustment just referred to is based upon the hypothesis of a flexible metabolism, itself in constant change and also capable of responding to changes in the environment. In the language of physiology, metabolism is here co-ordinated with irritability. In less technical language the living machine differs from an ordinary lifeless machine in the remarkable

* Adiposis, as is well known, would be etymologically more correct if it were written adipositas, but adiposis has been so long in use that it must be regarded as established. Adiposis Dolorosa has also perhaps a less formidable sound than has its Greek equivalent "Lipomatosis Algera."

extent of its power of repairing itself and adapting itself to the varying demands made upon it. But we must immediately qualify this statement. It is only the well-built living machine that can do this, and even the best of such machines can do it only to a limited extent. Here, then, lies the true conception of disease. Given a poorly made machine, or one of poor materials, and in time, no matter how favorable the environment, break-down (or disease) is certain to occur. Or, on the other hand, given a good machine, but an environment to which it is unable fully to adjust itself, and again disease and disaster ensue.

Disease, then, like ordinary life, is a condition; if the organism is well-made and capable, and adjusts itself without undue strain to its environment, health, or at least freedom from constitutional disease, is assured to it. But if it be poorly built, or of poor materials, it will ultimately fail to do its work well and disease will appear; or, it will fail utterly and death will supervene. Again, given a good living machine, its environment may change beyond its power of adaptation to it, as when a strong man is poisoned or falls into molten metal. In physiological language disease is to be conceived of as either imperfect metabolism or excessive (irreparable) interference with metabolism.

That nosology is the simplest, and also the most scientific, which regards diseases as either intrinsic or extrinsic, constitutional or environmental, and places diseased life in the same general category with normal life. If we accept this view and hold that disease is disturbance or abnormality, due either to defects in the living machine itself, or to environmental conditions or influences with which the machine cannot deal without exceeding its ordinary powers of adjustment and suffering thereby, we shall arrive at the fundamental conception of ætiology. We shall see that the causes of disease may be many, but that all causes, in the last analysis, must be either constitutional or environmental, or both.

At the present time there is remarkable activity in the domain of ætiology. The proximate causes of disease, the mechanism of infection, the distribution of specific germs, the sanitary effect of particular occupations or trades, such as stone-cutting and match-making, the influence of climate, diet, urban and suburban life, and the like, are being eagerly studied. Preventive medicine, working with the invaluable clews supplied to it by the germ theory of disease, is making progress that may fairly be described as immense, and is enriching almost daily our knowledge of proximate and practical ætiology. But it is in the field of ultimate or theoretical ætiology that the most remarkable achievements are now being made. In the course of the hot pursuit of immunity, which is one of the features of the day, much has come to light concerning the facts of cellular irritation, defence, and disease. It appears that in acute infectious disease—and at present our knowledge is largely restricted to the environmental diseases—there is first an invasion of the organism by something proceeding from without, it may be lifeless substances (poisons) or living organisms (germs, parasites, etc.). These act upon some or all of the living cells of the body, which in turn, by the exercise of their ordinary functions of adjustment, react upon the foreign matters. The extent of their reaction will depend upon the emergency and upon their own powers. The nature of the reaction will depend upon the particular irritation applied. The success of the reaction will depend upon its victory or failure. The reaction itself may make its appearance as functional disease or disturbance, such as fever, or as lesion, discoverable by structural changes in tissues or organs.

Ætiology here becomes the history of a battle in which the living machine struggles with an unfavorable environment. If it struggles easily, naturally, and successfully, the phenomenon is called ordinary life. If violently, and with fever, delirium, and slow convalescence, we must think of disease, but not necessarily of permanent lesion. If with obvious injury, and sequelæ such as indicate lesion, we must suppose that the machine has suffered beyond complete repair, though it may still continue to work. If death ends the struggle, it means that, however heroic may have been the effort, the mechanism proved inadequate to cope with its environment—unable to adjust its internal to its external relations.

Turning to the intrinsic or constitutional diseases we find ourselves dealing with a much more difficult phase of the subject. The special structure of the vital apparatus depends chiefly upon heredity, though its powers are influenced by environmental conditions, such as food, temperature, electricity, and moisture. What it is, precisely, that distinguishes the protoplasm of A from that of B we cannot say; why the one forms biliary or urinary calculi, while the other does not, though living under apparently similar conditions, we do not know. The microscope fails to reveal the important differences of molecular structure which must exist. Yet there can be no doubt that, if these could be seen, differences might be detected as great as those between any two machines intended to serve precisely the same purpose—for example, two clocks of different manufacture.

Enough has now been said to show that while we are yet very much in the dark concerning the ætiology of disease, we are certainly making headway in "the explanation of biological phenomena by showing that they constitute particular [and usually extreme] cases of general physical laws." The "general physical laws" prevailing in disease are the general laws of biology; the "particular cases" which diseases constitute are those of poorly built organisms struggling with ordinary environments, or, perhaps, as often, well-made organisms struggling with unfavorable environments; *i.e.*, normal organisms with abnormal conditions, or else abnormal organisms with good conditions. For a recent and suggestive treatment of the ætiology of disease see the Lumleian Lectures by P. H. Pye-Smith, delivered at the Royal College of Physicians, London, in *The Lancet*, 1892, Vol. I., p. 847 *et seq.* The debate now going on concerning *Immunity* (which see) should also be carefully followed.

William T. Sedgwick.

AGARICIN, AGARIC ACID.—The active principle of Boletus Laricis, Linn., White or Purging Agaric.

It occurs in white crystalline needles, soluble in alcohol, ether, and chloroform; boiling with water forms a gelatinous solution.

The use of this drug has been revived as a remedy for profuse sweating, especially the colliquative sweats of phthisis. Its effect is produced by its action on the glands themselves and not by any action on the nerve-centres. It is superior to white agaric on account of a more prompt and certain action and by not producing as much irritation of the digestive organs.

The dose is from $\frac{1}{12}$ to $\frac{1}{4}$ gr., increased to 1 gr.; it should be administered five or six hours before the expected sweating. It is given in pill or powder, combined with small doses of Dover's powder to counteract any tendency to diarrhœa. It may be administered by hypodermic injection. The following solution is recommended: Agaricin, $\frac{3}{4}$ gr.; alcohol, absolute, 80 ℥.; glycerine, 1 drachm. *Beaumont Small.*

AIX-LA-CHAPELLE (Ger., Aachen). Although the beneficial action of the thermal waters of Aix-la-Chapelle on a great variety of morbid processes has already been set forth (see art. Aachen, Vol. I. of this HANDBOOK), the chief *éclat* of this resort is undoubtedly due to the successful treatment there of syphilis. Many physicians have questioned whether the waters of Aix-la-Chapelle were possessed of curative properties unassisted by ordinary antisyphilitic treatment. Be this as it may, there is no doubt that better results are obtained at this spa, in all syphilitic diseases, than at any other watering-place in Europe.

It seems worth while to examine somewhat more closely the management of syphilis at Aix-la-Chapelle, for there is no theoretical reason why similarly good results should not be attainable at some of our own hot sulphur springs.

At Aix-la-Chapelle, mercury, properly given, is recognized as the true antidote to the poison of syphilis. And in agreement with the dictum of Sigmund, not only is the manifestation of mercurial poisoning held to be not needed, but syphilis is thought to be the more certainly cured in proportion as the body is protected from the toxic effects of mercury.

The Aix method of treating syphilis consists in the ancient practice of inunction, assisted by thermal baths and the drinking of mineral water.

The writer has closely followed the reasoning and rules given by Dr. Brandis, one of the most experienced physicians of the spa, as laid down in a series of articles published in the *Medical Press*. For more detailed information the reader is referred to "Aachen als Kurort," edited by Dr. Beissel, in association with the leading practitioners of the town, and published at Aix in 1889.

Dr. Brandis insists on three points:

1. The body must always be adequately prepared for the absorption of the mercury, and the gray ointment must always be used carefully and in sufficient quantity. The patients are directed to take a warm bath of half an hour's duration, and at a temperature of 95° F., so as to be prepared for the subsequent inunction. From this rule it may be necessary to deviate for various reasons. A very frequent cause which compels us to allow another treatment to precede the specific treatment is mercurialism, the result of previous incautiously applied mercurial treatment. If we are to undertake the inunction cure it is necessary to pay attention to the state of the skin. The Aix baths possess in a high degree the property of making the skin soft and absorbent. After the bath the patient must be most carefully dried, and immediately, in the bath-room, rubbed with gray ointment.

During the entire treatment it is advisable to allow the patients to drink the warm waters; two or three glasses should be drunk in the morning, and now and then in the evening also. In winter and cold weather they should be taken in bed; during the summer and on warm days, while walking about. Nevertheless, we must carefully notice if the internal employment of the waters disturbs the digestion, if it take away the appetite and thus interfere with the fulfilment of a very weighty indication, namely, the good nourishment of the body.

For removing the debility of the patients Dr. Brandis relies not on the use of the waters, but on the abundant drinking of warm milk, a measure the merits of which are not sufficiently appreciated.

Vapor-baths, followed by copious sweating, are indicated where the mercury no longer exercises its action on the healing process, and later on, in spite of continuous employment of co-operating remedies, appears not merely to remain inactive, but to give place to a new outbreak of the disease. As a rule, therefore, patients are directed, possibly after the twentieth inunction, to take a vapor-bath on three consecutive days, and after that to take the baths after each tenth inunction. During these days the rubbings must be discontinued.

As to the method of performing the inunctions, Sigmund's instructions are observed. But it is essential that competent rubbers do the work.

The ointment must be rubbed in with the entire surface of the hand, and with both hands conjointly, so that when, for example, the legs are subjected to the rubbing, the surfaces of the hands glide up and down simultaneously.

The use of gloves and pads is prohibited, as absorbing too much of the ointment. Mercurial poisoning in the rubbers is not observed. Every rubbing is to last fully twenty minutes, ten minutes for each half of the dose.

The instructions of Sigmund are as follows

On the first day rub both legs; on the second, both thighs; on the third, abdomen and breast; on the fourth, the back; and on the fifth, both arms.

Many patients, however, cannot endure the rubbing of the breast and abdomen; in such cases the sides of the body and the nates are employed. The daily dose varies with the body-weight and the susceptibility of the patients—between four and five grammes for adults, and from one to two grammes for children.

2. During a course of treatment the body must be maintained in good condition; exercise in the open air, spacious bedrooms, personal hygiene, good food in plenty are all to be thought of in this connection.

The treatment of the mucous membrane of the mouth is of great importance, for through its local treatment we must strive against the commencement of mercurial stomatitis.

Dr. Brandis employs a preparation made according to the following recipe:

℞. Pulveris aluminis,
Plumbi acetatis.....āā 30.0
Aquæ destillatæ..... 300.0
Misce et filtra.

This solution may be used diluted with pure water, or some aromatic water, about two dessertspoonfuls in a glass of water. The mouth must be regularly rinsed out, from the beginning of treatment, ten or twelve times a day, or even oftener; even when taking walks the patients must carry a small bottle of the liquid; and in urgent cases they must even use it repeatedly at night. After each meal the teeth must be brushed with a mixture of prepared chalk and camphor.

The author states that by most carefully carrying out these measures, we generally succeed in averting salivation; but occasionally it may happen that we may be obliged to suspend the inunction for a time. One thing more is to be observed—namely, we may accustom even highly sensitive patients to tolerate mercury. If we know beforehand that we have to deal with such, we begin with small doses of the mercurial ointment, and gradually increase to larger. Or if we have the misfortune to induce stomatitis, and are obliged to suspend the remedy, we postpone resuming it until all these symptoms have disappeared; we then begin again with small doses, and gradually rise to larger. A practical suggestion relates to ulcerative processes, so frequently observed in the course of syphilis. It is not always quite simple to distinguish mercurial from syphilitic ulcerations; they both occur in the most different parts of the mucous membrane of the mouth, and may look very like one another. Before all, this holds good of those mercurial ulcerations which occasionally appear on the tonsils and on the soft palate. Here frequently only long-continued observation can decide the matter; if, however, we are still in doubt, the inunctions must be suspended; the mercurial ulcers will then heal, whereas the syphilitic ulcers will be aggravated. They also behave differently when cauterized with nitrate of silver. The mercurial sore stands an energetic cauterization very well; in fact, its healing is furthered by it; whereas the opposite is generally the case with the venereal ulcers. Increased secretion of saliva may also occasion doubt, for at times syphilitic disorders which affect the cavity of the mouth directly produce salivation. Another disagreeable result of the inunction treatment is mercurial diarrhœa. This symptom sets in suddenly, the evacuations follow one another rapidly, there is pain and tenesmus, the stools are scanty and show mucus and blood. Treatment by opiates is indicated, but the inunctions must be at once interrupted.

Healthy persons lose in weight if subjected to mercurialization. In contradistinction to this, syphilitic patients gain in body-weight as soon as they enter the stage of convalescence. This applies to recent cases, as well as to those of old standing.

The inunctions must be employed for a sufficiently long time. As our task consists in healing the symptoms of the disease, and, as much as possible, in averting relapses, the earlier the syphilitically infected person is brought under mercurial treatment, the milder is the course of the illness.

3. Above all things, Brandis insists that we must not too soon dismiss the patient from treatment; indeed, never, until all symptoms have disappeared, up to the last vestige; and also, that even the slightest attacks must be

energetically treated from the outset. If experience shows us on the one hand that an inadequate treatment either fails to remove completely the existing symptoms, or, where complete recovery is achieved for the time, cannot avert later relapses, on the other hand we find that the desired result will be obtained in both directions, in those difficult and obstinate cases in which a long and energetic mercurial treatment must perforce be carried through.

In all ordinary cases the inunctions are prolonged eight or ten days beyond the time of healing of visible lesions, and the thermal baths need not be given for a longer period.

It is probable that Dr. Brandis goes a little too far when he claims that there are absolutely no contra-indications to anti-syphilitic treatment, as practised at Aix-la-Chapelle. The writer has visited Aix on several occasions, and he is convinced of the great efficacy of its waters, when used in conjunction with other remedies. But the very aged and extremely debilitated, as also the very young, should be judiciously treated at home, rather than incur the risks of a long and tedious journey to the ancient spa of Aix-la-Chapelle. Although it is an "all the year round" watering-place, the warm season should be given the preference. In the fall and winter months, the town is cold, dreary, and depressing, a circumstance worth remembering in sending patients there.

Edmund C. Wendt.

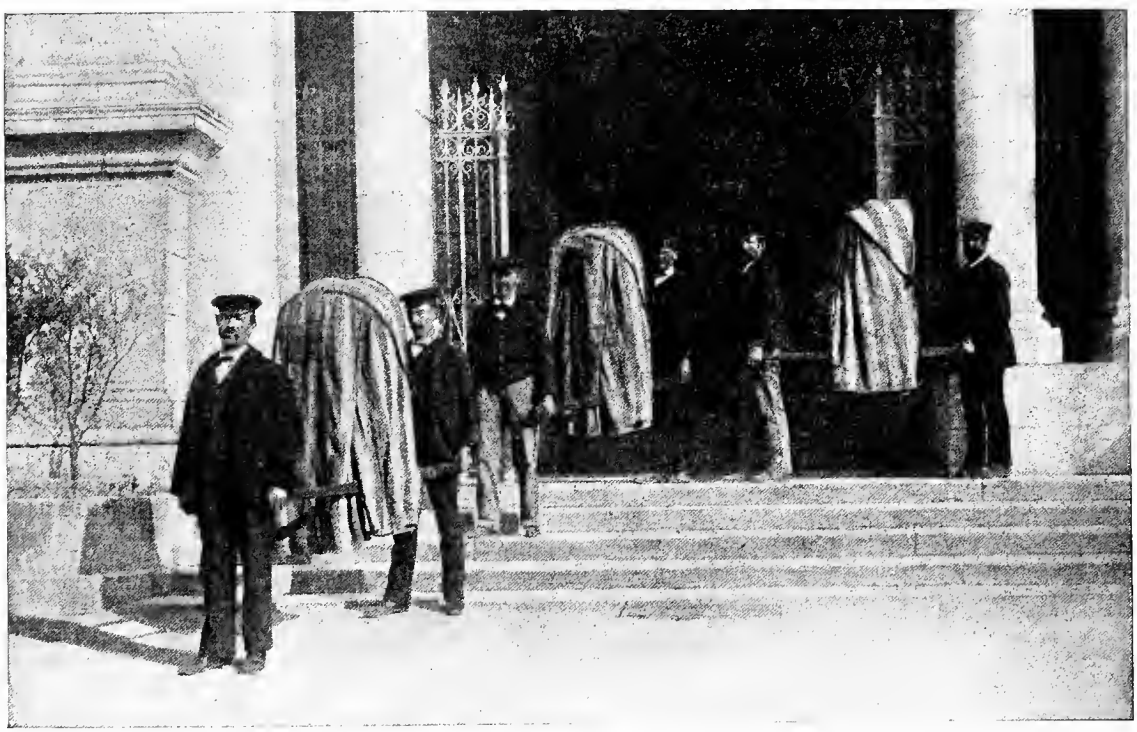

Fig. 14.—Method of Conveying Patients to and from the Thermal Establishment at Aix-les-Bains. (The Patients are Wrapped in Blankets only.)

AIX-LES-BAINS. In addition to the information already published (see Vol. I. of Handbook) concerning Aix, it may be well to give a supplementary description of certain features of this popular spa. It is not to be forgotten that no other resort in France is so largely frequented in the summer months by English and Americans as Aix-les-Bains. Dr. Linn (*The Climatologist*, June 15, 1892) has given a *résumé* of Aix in its modern development as a fashionable resort, from which the following account is taken:

The thermal establishment is one of the finest in France, and contains over fifty douche-rooms—general and local vapor-baths, swimming baths, and a large number of other baths, as well as the throat, eye, and ear douches, inhalation- and spray-rooms. Two thousand douches and one thousand baths can be, and often are, given daily.

The principal application of the Aix waters is by what is now called the "douche massage" (Forestier). The patient is taken into one of the large douche-rooms, where he is met by two of the attendants, male or female as the case may be. They seat the patient on a wooden stool, and, one taking the lower extremities and the other the back, they shampoo, knead, or rub according to the directions previously given by the patient's medical adviser. This is the "massage," in which all the attendants are skilled at Aix, it having been handed down to them from father to son, and from mother to daughter for many years past. The masseurs each have a hose under their arms from which they direct the water over the bather. It is this massage under the hot sulphur water that constitutes the principal treatment at Aix. The temperature of the water is varied by the physician's orders. As a rule, ten to fifteen minutes is the duration of this operation, when the patient is rubbed dry and enveloped in a blanket, put into a bath-chair and carried home by porters, who not only take him to his hotel, but also to his room, and place him in bed. This specialty of Aix is most important, as a rheumatic person seems to obtain more harm than good by having to dress after a douche or bath, and walk home afterward.

The waters of Aix-les-Bains are so abundant that they are allowed to flow away from an ugly public fountain. They act energetically by a stimulation of the cutaneous surface. It is, as it were, a purgation of the skin, making it eliminate whatever excrementitious matters may have been retained in the system, and relieving congestions of the deeper parts or organs, while giving a stimulus to the circulation in general. To this may be added the effects of the mineral elements in the waters taken into the system and blood both by drinking them and inhaling them during the douche and baths.

Dr. Linn accepts the usual indications for treatment, such as gout, rheumatism, skin diseases, syphilis, catarrhal affections of the respiratory passages, etc. But he has this to say as to contra-indications:

"It is easy to understand that all *acute* diseases would be better without the stimulation of the Aix treatment, and that its province is in *chronic troubles only*. Degeneration of the muscular fibre of the heart is a contra-indication, but valvular affections coming from a rheumatic cause improve at Aix, unless there be a tendency to syncope. Under this heading we think that patients should be warned against taking these powerful massage douches without medical advice, as they are apt to do great harm by an injudicious use of them. Many people insist on the masseurs giving them a vigorous treatment, when they have no proper power of reaction, and simply exhaust themselves, producing a state of feverish debility and weakness. Others, again, when the baths are crowded, get up at a very early hour to secure a douche or to have their morning free. We are of opinion that in many cases it will be found best to have a light breakfast and take the douche, as we do a sea-bath, at nine or ten in the morning or even later, and not attempt to turn out delicate people at five or six o'clock on a cool or wet day. As to the best time of the year to take this treatment, as a rule it should be during the summer months, *June to the end of September*, when the external warmth and greater equability of temperature, less risk of chill and its consequences, will allow patients who have rheumatic trouble, especially, to get the best results. It is remarked that July and August are the crowded months at the hydropathic stations, and many volumes have been written to try and persuade the good public that they would do better to come at other times; but the great mass are right, for very delicate people the *hot months are the best for bath treatment.*

"The establishment is, however, open all the year round, and those who like bracing air and want more reasonable rates can come at any time. The duration of the treatment has been rather arbitrarily fixed at three weeks or twenty-one days, but this depends on the case, as almost every patient demands a careful study by a physician, who alone can fix the time. It may be said, though, that many people get saturated with strong mineral waters in about three to four weeks."

Aix now has two *casinos*, the "*Cercle*" and the "*Villa des Fleurs.*" Good music and operas, reading-rooms, a race-course, pigeon-shooting, tennis, and other "distractions" are always provided at Aix. There are excellent opportunities for pleasant walks and excursions. The hotel and boarding-house accommodations are ample and highly satisfactory.

Concerning *Marlioz*, which is almost now a part of Aix, the same author gives the following information:

"Marlioz, an important sulpho-sodiac and bromo-iodurated water, is in the suburbs of Aix, and now forms part of it. It is a pleasant walk down the Avenue de Marlioz of about fifteen minutes, and the omnibus or tram runs there in less time. There are three springs, which are compared to the sulphur waters of the Pyrenees, like *Eaux Bonnes*. These springs are much richer in mineral elements than the hot waters of Aix itself. Patients live in Aix, but some rooms can be had close to the pretty little establishment in Marlioz. The specialty here is throat troubles. Its pulverizing or spray arrangements and inhaling-rooms are excellent and complete in every particular; there is also a good bathing department. The waters are highly efficacious in all chronic affections of the respiratory passages, chronic catarrhs, etc.; and form with the Challes water, which is also given in Aix, drawn from fountains in the chemists' or druggists' places like soda-water, a valuable adjunct to the other courses of treatment given in Aix-les-Bains."

Altogether the spa of Aix-les-Bains deserves the popularity which has been so liberally bestowed upon it by the exacting Anglo-American public.

Edmund C. Wendt.

AKINESIA ALGERA. Moebius[1] has given this name to an array of symptoms, among which the most characteristic is loss of power of movement as the result of accompanying pain, while no sufficient cause for the latter symptom has yet been found.

The cases which he reports were persons of neurotic inheritance, so-called *déséquilibrés*, in whom the disease manifested itself after mental over-exertion. In the one case neurasthenia, in the other hysteria, was present. In both cases the disease was quite protracted. The first case reported by him occurred in a man, a teacher in the gymnasium, thirty-three years old. The father suffered from paranoia. The patient during his youth was very excitable and extremely ambitious. No history of sexual perversion. In 1887 he suffered from headache and insomnia. In the spring of 1888 he was unable to carry on his work, and was sent to an institute. Subsequent to this there occurred a loss of memory for three or four weeks. After every movement the patient experienced a heaviness of the limbs and pains in the muscles. Improvement took place under prolonged rest, or the Weir Mitchell treatment. Following this a relapse occurred, during which the patient abstained from all movement of the limbs. The skin- and tendon-reflexes were present; the patellar reflex was quite marked. On the right side the ankle reflex was weak; on the left it was marked. There was found hyperæsthesia in the hands and forearms; no points of pain, however, were discovered. Organs of special sense normal. Every voluntary movement of the limbs and trunk was accompanied by severe pain, lasting for hours. These pains were most marked in the forearms. The head was free from pain, and there was no difficulty in moving it. There was a very slight muscular atrophy of the left hand, which was possibly caused by the pressure of pasteboard splints.

In the way of treatment, bromide of potassium, given in the evening in doses of from three to four grains, produced rest. Hypnotic suggestion was without result. Improvement followed after several months' rest. The tendon reflexes became weaker and finally normal, there remaining a weak ankle clonus on the left side. Subsequent to this, and following a considerable excitement, a relapse occurred, with subsequent improvement. The hands, however, remained quite painful.

The second case occurred in a woman, forty-three years of age, by occupation a teacher of music. A neurotic family history was given. From her twentieth year onward the patient had suffered from tremors, with semi-unconsciousness. The hands were painful, and were held in a flexed position. She also suffered from insomnia, and was incapable of mental work. The feet were painful, and walking was impossible. After suffering in this way for ten years, improvement set in, and the patient was comparatively well for a subsequent period of ten years. In the summer of 1889, probably as the result of over-work and excitement, a relapse occurred, from which she had not recovered up to the time of the report. There were found, extreme irritability, a forced position of the hands, and pain in the legs. The latter could be moved, but they soon became tired, and suffered from quite severe after-pains. Auditory and visual functions were normal. Hypnotic treatment without result. The patient twice attempted suicide, and finally gave evidence of mental trouble, with hallucinations of persecution. She subsequently died in an insane asylum.

In a subsequent publication[2] Moebius reports another case in which, in addition to the absence of motion resulting from pain, and really superseding it in importance, there was present an extreme degree of photophobia. We have here a condition very similar to that which has occurred in regard to motion, a condition in which the patient will not see because of the attending pain.

Moebius seeks to widen the term by calling it "Apraxia algera," or abeyance of the function of any or all organs because of the pain attending their functional activity.

In the last case this was very well illustrated by the very severe pain in the head attending any mental effort whatever. The case has a further interest in that the

report is taken from the "Autonosography" of the distinguished psycho-physicist, Gustav Theodor Fechner.

Longard[3] reports a case occurring in a young lady, aged twenty-nine. Her mother had suffered from arthritis deformans; her father, in 1874, became afflicted with paranoia. The patient had for years previously suffered from pelvic troubles (pelvic inflammation, uterine fibroids, metritis, etc.). The symptoms observed in this case were mental excitement and peculiar pains over the entire body, which later became so severe as to compel the patient to abstain from all motion. The psychical excitement also increased. During the later period of observation, retention of urine, marked constipation, and very obstinate insomnia showed themselves. Objectively, an increase of the tendon reflexes was found. The course of the disease was not materially altered during six months' treatment in the hospital. Improvement occurred later as the result of improved surroundings.

Longard calls attention to the fact that these cases of akinesia algera give the same clinical picture as was formerly described under the name of spinal irritation.

According to Moebius the affection is a functional or psychic one, and is not due to organic disease. The pains he regards as hysterical, or pain-hallucinations. The disease itself is not, however, a pure hysteria, but may be regarded as an analogue of the general anæsthesia described by Krukenberg, Heyne, and von Ziemssen. The cases reported by W. Neftell in 1883, and called by that author Atremia, are regarded by Moebius as similar to his cases.

The prognosis is not very favorable. In the matter of treatment the best thing to do is to accede to the wishes of the patient for rest.

S. P. Kramer.

ALASSIO. A winter health-resort on the Italian Riviera, which is lately claiming an increased share of attention. It is prettily situated, but owing to its comparative newness the accommodations for invalids are far from perfect. The only reliable meteorological data available are those of Dr. Schneer ("Alassio and its Climate," Turin, 1878) and a synopsis published by Dr. M. G. Foster (*British Medical Journal*, November 7, 1891). Dr. Foster, who is now practising at San Remo, informed the writer that the authorities of Alassio appeared to lack energy in effecting reforms, more particularly from a sanitary point of view. Dr. Foster spent two winters at Alassio, and did not observe any typhoid fever there; but it is said to occur there every summer. There is no system of drainage, the excreta being collected in cesspools. The drinking-water is hard, but as to organic impurities reliable data are not at hand to justify its condemnation or acceptance. Sparks ("The Riviera," London, 1879), claims that the water is good and potable.

Alassio is on the north shore of the Mediterranean, about equidistant from Nice and Genoa. It lies at the head of a curving bay, which is some five miles wide. The town has about 6,500 inhabitants. Its latitude is about the same as that of San Remo. Dr. Foster's description is here reproduced, as it is accurate and devoid of local bias:

"Without the gates of the city proper at either end stretches a suburb composed of dwellings of the Italian population mingled with a few villas. Each of these suburbs contains a hotel situated facing the sea, while a third is placed about a hundred yards behind the main street of the town. The villas of the English residents are dotted over the lowermost spurs of the encircling hills. The hills form an unbroken semicircle round the town. Their greatest elevation is on the north (1,963 feet). Numerous valleys run up among the lower spurs of these hills, but none pierce them.

"Alassio thus secures good protection from the north, west, and southwest. The seashore is generally windy, but in the valleys running up among the hills the wind is rarely severely felt, and on most days the air in these situations is almost entirely still."

The records of temperature (as given by Foster) are as follows:

"October has a	mean	temperature of	61.9°	Fahr.
November	"	"	54.3°	"
December	"	"	49.7°	"
January	"	"	47.3°	"
February	"	"	48.2°	"
March	"	"	52.3°	"
April	"	"	56.4°	"
May	"	"	64.3°	"

"The mean temperature of the three winter months is therefore 48.4° F."

Turning now to the rainfall observations, the records give the following results:

"October shows an average of 7 days on which rain fell, an average rainfall of 93.1 millimetres, and a mean relative humidity of 55.2.

"November shows an average of 8.6 days on which rain fell, an average rainfall of 163.7 millimetres, and a mean relative humidity of 58.

"December shows an average of 5.6 days on which rain fell, an average rainfall of 43.3 millimetres, and a mean relative humidity of 55.4.

"January shows an average of 4.3 days on which rain fell, an average rainfall of 60 millimetres, and a mean relative humidity of 52.9.

"February shows an average number of 4.8 days on which rain fell, an average rainfall of 70.9 millimetres, and a mean relative humidity of 55.7.

"March shows an average of 6.6 days on which rain fell, an average rainfall of 50.7 millimetres, and a mean relative humidity of 57.9.

"April shows an average of 10.8 days on which rain fell, an average rainfall of 111.9 millimetres, and a mean relative humidity of 62.8.

"May shows an average of 5 days on which rain fell, an average rainfall of 46.4 millimetres, and a mean relative humidity of 63.1.

"Fog has been recorded on 14 days in the six winters."

In his summary of what class of cases are likely to derive benefit from a winter residence at Alassio, Dr. Foster expresses the following opinions:

"The climate of Alassio possesses those advantages which a tolerably high and fairly equable temperature, abundance of sunshine, and freedom from fog can give. Cases of gout and chronic rheumatism do well there. Cases of heart disease certainly appear to do well; they eat and sleep better, and, with ordinary precautions, attacks of secondary bronchitis can be prevented. Cases of bronchitis and emphysema, with care, keep very free from winter cough. Cases of phthisis require very careful selection. Early cases, with limited consolidation and only slight fever, generally do well. Later cases with cavities seem to show improvement, the cough and expectoration diminish, and, since the patients can generally pass a fair amount of time in the open air, the appetite and sleep are both improved. Cases characterized by frequent hemorrhage, with only slight physical signs, seem generally to do well. Owing to the proximity of the principal hotels to the sea, the effect of the climate varies in different cases; some patients sleep badly by the sea, and thus lose much of the benefits; others again sleep better there than elsewhere. Weakly and strumous children certainly show great improvement, as they can pass a large amount of time on the seashore. Finally, with regard to that numerous class of cases which are sent to the Riviera under the generic title of nervous breakdown, some cases seem to show great improvement and regain their lost health, while in other cases all the symptoms appear to become aggravated."

Alassio is a somewhat cheaper place to live in than many of the other Riviera stations.

Edmund C. Wendt.

ALEXANDER-ADAMS OPERATION. The operation of shortening the round ligaments for the cure of prolapsus uteri was proposed by Alquié, as applicable to the cure of retroflexion. Aran, according to Tillaux, suggested this operation. The same thought occurring to Freund he performed the operation on the cadaver. It was first performed on the living subject by Alexander, of Liverpool, in 1881. Adams, of Glasgow, performed it in 1882, without a knowledge of Alexander's operation. During the past ten years the operation has been done hundreds of times, and principally in America. This operation has been severely criticised by many, both here and abroad, but on carefully looking up these criticisms it was found that they were wholly based on theoretical grounds, or had been brought forward by those who had not done the operation sufficiently often to be familiar with it or its results. Those who have done the operation the most times and have seen the excellent results that follow in properly chosen cases, are its most enthusiastic advocates. Hysterorrhaphy is advocated by some, *especially* by operators on the Continent, in preference to the Alexander-Adams operation. I have had considerable experience with hysterorrhaphy for the relief of retroversions and flexions, both with and without adhesions, attended both with and without prolapsed and adherent ovaries. My results have been excellent, there having been but one failure and one death in quite a considerable number of cases.

As far as I can ascertain we have no data relative to the effect of pregnancy on the adhesions produced between the parietal peritoneum and the peritoneum covering the uterus. With the other operations inside the abdominal cavity that secure the forward position of the fundus uteri I have had no experience. But opening the abdominal cavity is not wholly without danger, consequently the Alexander-Adams operation is preferable, especially as it will accomplish, in just as satisfactory a manner, everything that an intra-abdominal operation will do, and it is practically free from danger.

Indications for the Operation.—1. For the cure of uncomplicated retroversions and retroflexions where the patient is desirous of getting rid of wearing a pessary which necessitates her consulting a physician at stated intervals and makes her feel that she is still on the invalid list. Patients often choose this operation to avoid wearing a pessary.

2. For the cure of retroversions and retroflexions where a prolapsed ovary or ovaries prevents the wearing of a pessary, either by mechanically diminishing the transverse pelvic space, thus causing a pessary to ride obliquely instead of horizontally, or where, through sensitiveness of one or both ovaries, a pessary cannot be tolerated.

3. For the cure of retroversions and retroflexions with prolapse in the second degree, and for all cases of procidentia; it being understood that whatever plastic operation on the vaginal walls or perineum is called for, shall be done at the same sitting. As this operation diminishes a rectocele, but increases a cystocele, I advise doing the Alexander-Adams operation before operating on the vaginal walls. All operations on the vaginal walls can be done without bringing any strain on the round ligaments, just fastened in their new relations. If a trachelorrhaphy is called for it should be done at the same sitting with the Alexander-Adams, but prior to it, as all dragging down on the round ligaments should be avoided.

4. For the relief of lateral displacements, retroversions, and retroflexions with adhesions. Often, after packing faithfully for weeks, sometimes for months, in the Sims position, we are unable to relieve this class of cases, the more or less fixed position of the uterus and our inability to keep it forward in anteversion being due to adhesions between ovary and tube, or ovaries and tubes, and peritoneum covering uterus, broad ligaments, rectum, or intestine. In my experience these cases give a history of septic peritonitis following labor, abortion, or salpingitis. In opening the abdominal cavity in cases where there has been for months or years retroposition with adhesions—often cases of pyosalpinx with a history of repeated attacks of peritonitis—I have over and over again been surprised at the ease with which the uterus could be anteverted by the intra-abdominal fingers, and in a good proportion of the cases the fundus would stay forward without being supported. This led me in 1889 to make attempts, under ether, through the rectum, to replace uteri retroverted or retroflexed and adherent, after the packing had been thoroughly tried. The index finger of the left hand is passed up the rectum, the patient being *thoroughly* etherized, flat on the back on an even hard surface, with the knees well separated and the thighs drawn *forward* to an angle of forty-five degrees with the table. The index finger is passed up until, with the aid of counter-pressure by the right-hand fingers through the abdomen, it feels the whole of the posterior surface of the uterus, the posterior surface of the broad ligaments, the fundus, the ovaries, and the tubes. In this way all the pelvic structures can be actually examined and their relations to each other, changes in size, etc., can be more accurately determined. Then gently, but slowly, the uterus is anteverted. At times the adhesions are overcome with difficulty. Dr. Conant and myself worked over one hour in breaking up the adhesions in one case, and half an hour is no unusual time to be consumed in replacing the uterus. Then, while the uterus is held in position by a Kingman's or Emmet's uterine repositor, the cervix being pushed well back into the post cul-de-sac, an Alexander-Adams operation is done. The uterus is thus held upward, non-flexed, and forward while the raw surfaces of the peritoneum are becoming adherent to each other.

In some cases it is impossible to correct the retrodisplacement, owing to the quantity, quality, or location of the adhesions, without using more force than would be safe. In such cases, if the condition of the patient demands interference, or if she is sterile and willing to run the risk, cœliotomy should be done, all adhesions broken up, and the uterus fastened in anteversion by hysterorrhaphy. This combination has worked admirably in cases where it was impossible to satisfactorily replace the uterus through the vagina or rectum.

When, the patient being under ether,—and a diagnosis not made when the patient is thoroughly anæsthetized should not be accepted as final,—the tubes are found to contain fluid or are much enlarged, I think it advisable not to interfere with adhesions, for fear of rupturing the tube or tearing away the fimbriated extremity, thus allowing septic material to escape into the peritoneal cavity.

5. While witnessing Dr. Conant make several dissections for the round ligaments, I was surprised to see how securely and evenly the internal abdominal rings were closed when the round ligaments were drawn out, and it occurred to me that the Alexander-Adams operation might be done for the radical cure of hernia.

Dr. Conant wrote me the following, under date of August 24, 1892: "I have had one case for radical cure of hernia by the Alexander operation. The case was one of double inguinal hernia in a young girl of nineteen. I practically did the regular Alexander, except that I was somewhat puzzled to find the round ligament on the right side, owing to the size of the sac. The result of the operation was very gratifying. Previous to the operation, which was done last spring, she was unable to work, but since the operation she has been at work for the last three months. She is in good health, although she has some pain at times in her left side. I have examined the case within a week and found a firm cicatrix about the pillars of the rings on both sides. She never wore a truss." In October, 1892, I did an Alexander-Adams operation for procidentia of six months' standing, and left inguinal hernia. At the present time (January, 1893) the uterus is in perfect position, there is complete relief of all symptoms, and there has been no symptom of a return of the hernia.

6. In two cases I have done the Alexander-Adams operation to prevent incarceration of a fibroid which threatened to take place at any time, the growth of the tumor being very rapid. In both cases severe symptoms from pressure were present. In both cases the fibroid, which

was interstitial, in the posterior uterine wall, was got out of the hollow of the sacrum with great difficulty. In both cases, one a woman who had borne five children, the other not married, the ligaments were as large as a No. 2 Faber lead-pencil. The first case was operated on in March, 1891 (reported in list of cases). Examination one year later revealed the uterus to be in perfect position, with a marked diminution in the size of the fibroid. (Treatment with the idea of arresting the growth of the fibroid had been continued throughout the year.) The second case was operated on in June, 1892. At present (October, 1892) the uterus with its large fibroid is up out of the pelvis, and there is relief from all former distressing symptoms.

Those opposed to this operation bring forward the following objections:

1st. That the ligaments are often absent.

2d. That there is great difficulty in finding the ligaments.

3d. That it is a dangerous operation.

4th. That it prevents the usual course of pregnancy, causing it to terminate in abortion.

5th. That after pregnancy the uterus returns to its former malposition.

6th. That it may give rise to serious secondary symptoms or conditions.

7th. That it is limited in its application.

8th. That it will soon become obsolete.

1. In my experience with over one hundred and twenty-five cases, I have never failed to find the ligaments except in one case. This was among the very first operated on. No doubt the ligaments were present and of good size, but I failed to find them. Since then I have operated successfully on a case where the operation had been attempted, but abandoned on account of the inability of the operator to find the ligaments. The patient was told that she had no round ligaments. I agree with Dr. W. M. Conant in his statement, that "The ligaments are never wanting provided there is a uterus." They may be very small, but they are there and are of a good size nine times out of ten after they are drawn out.

2. The difficulty in finding the ligaments depends entirely on the experience of the operator. The description of the operation given in many text-books is misleading. The beginner is led to think that he is about to do an operation the success of which depends on his ability to recognize each layer of tissue and every vessel and nerve from the skin down until he has reached the aponeurosis of the external oblique muscle. Now this is at times difficult to do with thin abdominal walls, and often so in a fat patient, and it is no wonder that the beginner gets wound up with a round turn just at the time when it would mean success for him to have some fixed and easily recognized landmarks. Many descriptions of the modus operandi of the Alexander-Adams operation remind me of the old way in which an abdominal section was described—where layer by layer the tissues were cut through on a grooved director with a dull knife down to the peritoneum, more time being used up in getting inside the peritoneum than is now often consumed in getting in, doing what is necessary, and getting out. If the operator will mark, read, learn, and inwardly digest Alexander's excellent article, fully describing the operation, in the "Transactions of the International Medical Congress," 1887, vol. xi., p. 742, and Mundé's admirable article in the *American Journal of Obstetrics*, 1888, he will have no difficulty in finding the ligaments.

3. Alexander has operated eighty-four times and has never had a death, and in the article above referred to he says, "I no more expect a death from it than I expect a death from an amputation of the finger."

Mundé has operated thirty-seven times and has never had a death nor any unpleasant results.

Reid has operated thirteen times with no death.

Edebohls has operated twenty-nine times with no unpleasant results.

Newman, in 1888, read a paper on this subject, and estimated there had been up to that time three hundred cases operated on. Of this number he knew of three deaths.

W. M. Conant has operated over thirty times with no death.

F. B. Harrington has operated twenty-five times with no death.

Kingman has operated over twelve times with no death.

Burrage has operated over sixteen times with no death.

J. G. Blake has operated twenty-five times with no death.

J. B. Swift has operated thirteen times with no death.

I have operated over one hundred and twenty-five times with two deaths. The first was due to acute sepsis. The abdominal cavity was opened while drawing out one of the ligaments. This was among my first operations and before the rigid asepsis now employed was used. The second was due to pneumonia and occurred six days after the operation. The wounds had healed by first intention throughout. The various journals for the past few years have contained abundant testimony like the above.

In over two hundred and forty-six cases operated on in Boston, most of the cases having been operated on since 1888, I have been able to learn of only three deaths, two mentioned above and a third, due to sepsis, the bladder having been opened on the left side, either by the knife or a deep stitch. On this followed infiltration of urine with pelvic abscess, to which the death was to be directly attributed. In nearly a thousand cases collected by Dr. W. M. Conant he found a record of only seven deaths.

4 and 5. These can best be answered in one. That it does not prevent the usual course of pregnancy can, as Dr. Conant has shown, be best determined by a reference to the cases reported. He collected twenty cases; seven by Alexander, five by Mundé, two by Conant, two by Johnson, and four unknown. Alexander claims that pregnancy is favored by this operation and that there is little danger of the return of the former malposition. Dr. Mundé wrote Dr. Conant as follows: "In four the uterus remained in its normal position after confinement. One, done for prolapse, became pregnant soon after the operation and after the confinement the prolapse returned. This is the *only* case where the displacement, retroversion or prolapse, returned after the operation, so far as I know."

Dr. Conant's first case was the first one he operated on; about a year after the operation she was married and was unwell only twice, when she became pregnant. She has been delivered at term. My two I will report here at some length.

Case I.—Diagnosis under ether: Ruptured perineum; retroflexion; bilateral laceration of the cervix; left ovary prolapsed and adherent at a point close to the uterus at the base of the left ligament. By packing, the uterus was got into normal position, but a pessary could not be worn on account of the prolapsed and adherent ovary. She was advised to have the lacerated cervix operated on and to have an Alexander-Adams operation to relieve the sagging and dragging down. *She had aborted four times since her last confinement five years ago.* The operations were done in February, 1890, and perfect results were obtained. In a few months she became pregnant and was delivered at term. The family attendant answered the following questions.

Length of labor? "About one and three-quarters hours."

Sex and weight of child? "Boy; nine and one-half pounds."

Character of labor? "She had good pains, better than ever before."

Puerperium? "She remained in bed fourteen days. She flowed a good deal—not post-partum hemorrhage,—but during her stay in bed she lost considerable blood, although there was good and permanent contraction of uterus. She was weak on getting up, but nothing of interest occurred. She nursed the baby." One year after pregnancy took place she was examined at my office. The symptoms for which the operations had been done had never returned. The uterus was in per-

fect position. Cavity measured two and one-half inches. No discharge from vagina or cervix.

Case II.—Sterility. Diagnosis under ether; Retroversion with adhesions; left ovary prolapsed and adherent; chronic endometritis.

She had been married five years. Never pregnant. Sought relief for the sterility and for back-ache and pain in the left ovarian region. January, 1891, the uterus was forcibly restored to its normal position and the round ligaments were shortened. Both sides suppurated, but the result was perfect, except that the uterus was drawn over toward the right side. She became pregnant two months after the operation and was delivered at term. Examined at my office one year after confinement. Uterus was in the same position that it was directly after the operation. Left ovary could not be found. Since the operation there has been complete relief of all back-ache and pain in left ovarian region.

6. I have had four cases in which pneumonia followed this operation, but I could see no connection between the operation and the lung trouble. All four occurred in hospital practice, during the winter, and at a time when the grippe was very prevalent. One case, noted above, died. I have had several cases in which pneumonia followed cœliotomy and in no way, so far as I could see, was it connected with the operation.

Cases of cystitis have been reported, but I have seen but one such case, and I attributed it to washing out the bladder. For the relief of frequent and painful micturition the nurse in my absence was ordered to wash out the bladder, and a violent cystitis followed, lasting two weeks. In quite a large proportion of the cases operated on by myself there has been bladder-trouble, showing itself in frequent and painful micturition with scalding referred to the meatus and urethra, and suprapubic distress or dull pain. In some cases there has been tenesmus with the forcing out of a few drops of blood at the end of micturition. In these cases the urine has been of a high color, high specific gravity, and loaded with mucus and urates.

Unfortunately, in almost every case after this operation there is inability to empty the bladder for the first twenty-four hours, and sometimes it is three or four days before the catheter can be dispensed with. But in some of my cases the above symptoms occurred when no catheter was used, and whenever the catheter *was* employed the greatest vigilance was exerted to secure cleanliness. In the cases where no catheter was used, the symptoms were usually less severe, lasted a short time, and were more amenable to treatment. Still, the severest cases got well after a time. One class of these cases is peculiar, and points to the fact that the operation is directly the cause of the bladder trouble. In this class there had been no previous bladder trouble, no retention, and no catheter had been used. The bladder symptoms appeared, but not for eight or ten days, and in one case they did not appear for three weeks after the operation. I have gone thus extensively into the bladder trouble following this operation, as it is a strong point with the opponents of the Alexander-Adams operation. For twelve years I have seen a great deal of gynecological surgery, both hospital and private, and at the hands of the very best men, and have known the above-mentioned bladder symptoms to be present, even severe attacks of cystitis, over and over again, after perineorrhaphy where the catheter was used, after trachelorrhaphy and operations on the vaginal walls where no catheter was used, and after cœliotomy both where the catheter was and where it was not used.

I have known of one case of double phlegmasia alba dolens. It followed an attempt to do an Alexander-Adams operation, but the ligaments were not found. Drainage was used and was probably the cause of the trouble. In almost all of my cases where the nerve was broken or injured in drawing out the ligaments there was more or less neuralgic pain in the neighborhood of the incision. At times the pain would extend upward as high as the floating ribs, at times it would reach over the thigh and down the sciatic nerve and its branches. These pains were complained of usually after the patients were up and about, or after they had got home. In these cases an attack was pretty sure to come on at menstrual periods. These attacks of pain come on every day or two, lasting from a few minutes up to an hour or two, but in the severest cases give no trouble after a few weeks. A burning feeling in the incision, with numbness in the mons veneris lasting from a few days up to a week or ten days, was not uncommon. It occurred in at least ten cases. Hæmaturia occurred in three cases. They were cases of retrodisplacement with extensive adhesions, and the forcible breaking up of these adhesions, as pointed out by Dr. Conant, may have injured the ureters. The hemorrhage was small and occurred only during the first twelve hours after the operation.

The liability to hernia has been brought forward as an objection to the operation. If the operation is properly and successfully done no hernia can occur, as the internal abdominal rings are completely and securely covered over by the anterior surface of the broad ligaments.

Unfortunately, sloughing of the wound is not uncommon in the experience of all. Whether the fault is in the ligament, its vitality being poor, whether the fault lies in the poorly vitalized aponeurosis to which we fasten the ligaments, or whether the damage is due to the bruising and stretching of the ligaments during extraction, has not yet been settled. That this suppuration is not due to the operator or to the variety of suture material used, has been proved. After looking over the cases it was found that suppuration occurred in thin as often as in fat abdominal walls. In the first twenty-five cases done by Alexander, nearly one-third sloughed on one or both sides; in the remaining fifty-nine cases only two sloughed. Sloughing of the wound delays convalescence, and often sinuses remain until the sutures put in to hold the ligaments are discharged or removed. Sloughing of the wound does not interfere with a perfect result as far as the position of the uterus is concerned. Sloughing of the wound is not dangerous if the pus is let out as soon as formed. I have never known an instance where peritonitis or any intra-abdominal symptoms followed sloughing of the wound.

7. Enough has been said above to show that it is not limited in its application.

8. It certainly will be a long time here in Boston before this operation becomes obsolete. Those who see much of gynecological practice are doing the operation more and more. In proportion to its size I doubt if there is a city in this country where more men are doing this operation than in Boston.

A success surgically and a success therapeutically are two very different things. Those who are most pleased with the operation are those who know enough about gynecology to operate on proper cases.

Anatomy.— "The round ligaments are two fibro-muscular cords that arise from the upper end of the uterus anteriorly and run through the superior portion of the broad ligament to the internal ring and pass through the inguinal canal, and terminate in fibrous expansions over the symphysis, becoming lost in the mons. They can, therefore, be divided into three parts— the portion external to the canal, the portion in the canal, and the portion within the pelvic cavity. The pelvic portion is attached to the upper angle of the uterus, in front of and just below the origin of the Fallopian tubes. It runs in the anterior fold of the broad ligament, and comes upward, outward, then forward and inward to the internal ring. After it leaves the broad ligament it is covered with peritoneum and lies in the lateral wall of the pelvis, crossing the external iliac artery. At the ring the epigastric artery is to the inner side, and at the operation can be easily felt pulsating. At first the ligament is large, but in leaving the broad ligament it is smaller and rounded. In the canal it tapers gradually, and has the same relations as the spermatic cord. As it leaves the external ring, the ligament runs near the outer side of the pubic spine and then each breaks up over the symphysis into thin sets of fibres. A branch of the genito-crural nerve lies to the outer side of the ligament as it emerges from the ring.

The length of the ligament is about four inches. Besides areolar tissue and vessels, the ligaments contain, chiefly in their inner third, plain muscular fibres which are prolonged into them from the outer muscular layer of the uterine wall. Each ligament receives a covering from the peritoneum which projects into the internal ring as the canal of Nuck. When traction is made on the round ligaments the uterus is pulled forward and upward; the broad ligament resumes its normal position, and a prolapsed tube and ovary are lifted out of the posterior cul-de-sac. There seems also to be puckering up of the broad ligament." (W. M. Conant.)

Preparation of the Patient, Operator, Instruments, Ligatures, Sponges, etc.—Thirty-six hours before the operation one ounce of castor-oil is administered. After this nothing but gruel is allowed for nourishment, and the patient is kept in bed. The evening before the operation the patient takes a tub-bath, and the abdomen below the umbilicus and the pubes are thoroughly washed with soapsuds and all the hair shaved off; then the parts are washed with ether, then with a 1 to 1,000 solution of corrosive sublimate, and a corrosive sublimate pad (1 to 3,000) is fastened over the whole lower abdomen and pubes. This pad is not disturbed until the patient is on the table ready for the operation. Every six hours, beginning thirty-six hours before the operation, the vulva is washed with a 1 to 1,000 solution of corrosive sublimate and vaginal douches of the same strength are given. Two hours before the operation two ounces of whiskey are given by the rectum, and one hour before administering ether one one-hundredth grain of atropia is given by the mouth. In several years' experience with atropia, it has been found that when it is administered as above, seven-tenths of the patients do not vomit on coming out of the ether, and in part, or wholly, it prevents the filling up of the mouth and fauces with mucus. While the patient is being etherized, the instruments, ligatures, sponges, and towels are placed in an Arnold steam sterilizer. The room, table, and clothing has been prepared as if a cœliotomy was to be done. The operator and assistant remove their outside garments, substituting freshly washed cotton trousers, frock, and canvas shoes. The hands and forearms are scrubbed in soapsuds with constant rinsing for ten minutes by the watch, great care being taken to clean the finger-nails; then they are washed in a saturated solution of permanganate of potassium until of a dark mahogany color; then, finally, the permanganate stain is removed by peroxide of hydrogen or oxalic acid. If at any time after this the fingers touch anything or any part of the patient that is not aseptic, the hands are washed in running water with brush and soap. When the patient is etherized, the bladder is emptied and the vagina and vulva are vigorously washed with soap and water. Dr. W. L. Burrage's method of cleaning the vagina is a good one. He takes a piece of moderately soft soap as large as a French prune, introduces it with a little water into the vagina, and with the index and middle fingers of the right hand he thoroughly lathers the whole vaginal mucous membrane. After washing out the vagina and cleansing the vulva with a hot 1 to 1,000 solution of corrosive sublimate the uterus is put in extreme anteversion. If adhesions are present they are overcome as mentioned above. As it has been my experience, backed up by that of the pathologist, to find chronic hyperplastic endometritis in every case where an Alexander-Adams operation was called for, I dilate the cervix, thoroughly curette the endometrium with the sharp curette, and pack the uterine cavity with sterilized gauze, on which iodoform or dermatol, as recommended by Burrage, has been freely dusted. The gauze is allowed to stay in the uterus from a week to ten days. By using Burrage's uterine speculum no trouble is experienced in introducing the gauze.

All being ready for the Alexander-Adams, the corrosive sublimate pad is removed, a Kelley pad is put under the patient, and clean rubber sheets are put above and below to protect the patient and conduct the water into the pad. Between the thighs a Ferguson speculum is placed to conduct all wash water into the pad. The abdomen is thoroughly scrubbed with soapsuds and then washed off with hot water that has been boiled and filtered. From the time the first incision is made until the wound is closed the field of operation is very frequently flooded with hot water that has been boiled and filtered. The sterilizer is now brought into the operating-room, and hot steaming towels are placed around the field of operation. The instruments are taken out on trays, which are put in pans filled with hot water that has been boiled and filtered. The sponges, made of folded gauze, are taken from the sterilizer and put in covered pails containing hot water that has been boiled and filtered.

Operation.—Two, and only two, landmarks need be kept in mind. One only is really *necessary*, but as some operators get into the peritoneal cavity without apparently knowing the fact until they are there, the second landmark, the observance of which will surely keep them out, is given. First of all, locate the pubic spine. This is usually done with ease, and it is only exceptionally that the spine is not pointed enough to be readily recognized. When, either through fat in the abdominal walls or lack of development, the spine cannot be located with entire satisfaction, make an incision an inch long through the skin and subjacent tissues over where you think the spine should be, and the definite location of it will then be settled by the finger. I am thus particular about this because I have never seen anybody fail to find the ligaments when they kept the finger and their mind's eye on the pubic spine. The pubic spine located, cut down at once to the aponeurosis of the external oblique muscle (see that the lower end of the incision stops just over the pubic spine). This white glistening tissue cannot be missed. This is the second landmark, and if the operator keeps above this he will never unintentionally enter the abdominal cavity. Stop all bleeding as you go along, so that the aponeurosis may be kept white and clean. Use as few pressure-forceps as possible, as union by first intention is desirable. Clean up the aponeurosis for an inch and a half from the pubic spine, and then with the index finger on the spine the ligament will be found without any difficulty. Sometimes the external ring can be seen, usually it can be felt; now and then the intercolumnar fascia is so strong that no ring can be seen or felt. In this latter case if the fascia is cut through just in front of the pubic spine, a mass of fat will protrude, and this is the guide to the ligament. Grasp this fat with the tissue about it, unless the ligament is seen, in which case grasp the ligament, and tease it out of the ring, or slit up the aponeurosis a little way and tease the fat and tissue out of the canal. If one is careful to get hold of all the fat and tissue, the ligament will soon be seen after a little traction on these tissues. Separate the nerve from the ligament, being careful not to injure it by rough handling or by sewing it to the aponeurosis when fastening the ligaments. Draw out both ligaments until the uterus, by vaginal examination, is found to be in the desired position, then fasten them to the pillars of the ring or to the aponeurosis, if the canal has been slit up. (I have never seen the ligaments fastened to the pillars of the ring.) The slack of the ligament may be cut off near where it is fastened and entirely removed, or it may be folded into the wound and fastened there by the sutures that close the incision, or by separate sutures, or it may be tied in a hard knot to the slack of the opposite side, and both buried and sewed into the incisions that have been prolonged so as to meet. I prefer the second method, if the ligaments have not been crushed or bruised in getting them out. If I fear that their vitality has been impaired, the first method is employed. Attention to cleanliness should be the same as if cœliotomy was being done, as it may be necessary to free the ligaments from adhesions throughout the whole length of the canals, and the peritoneal cavity may be opened; then, too, healing by first intention is the desideratum. If a ligament should break, slit up the aponeurosis to the point where the ligament dips down to enter the internal ring, and at the internal ring search for it. If it cannot be found at the internal ring it will be necessary to do a cœliotomy to secure it.

Catgut, silk, and silkworm-gut may be used in suturing the ligaments. Silk, silkworm-gut, and wire may be used in closing the incisions. Wherever ligatures are needed I prefer silkworm-gut for three reasons: 1st, It can be made perfectly aseptic; 2d, it is never absorbed; 3d, it is less irritating than any other suture material. Whatever kind of suture material is used, four sutures are needed to securely fasten each ligament, two on each side. These sutures are cut short and buried. Care should be exercised not to tie these ligament-sutures too tight, neither should they catch up too much of the ligament for fear of strangulation with following suppuration.

Preparation of Ligatures.—Silk is soaked in ether for forty-eight hours, and it is then boiled for two hours in a 1 to 20 carbolic acid solution, or for the same length of time in filtered water. It is kept in absolute alcohol. Only as much as will be used at any one operation is taken from the alcohol and sterilized. If any of this is left over after having been handled, it is boiled again for two hours before being used.

Catgut is soaked in ether for several days in the coils as it is bought. Then it is wound on glass buttons, each button taking one coil. It is then boiled in alcohol in a jar with the cover on, in an Arnold sterilizer, for one hour on three consecutive days. It is then removed from this alcohol with sterilized forceps and put in absolute alcohol. Only one button is taken from the alcohol for an Alexander-Adams. This is again sterilized by boiling in alcohol in an Arnold sterilizer for half an hour previous to the operation.

Silkworm-gut is first thoroughly boiled for two hours in filtered water. Then it is put in absolute alcohol. Ten or twelve strands are put with the instruments in the sterilizer half an hour before the operation.

After closing the incisions, powdered boric acid and iodoform are thickly dusted over both lines and kept in place by square pieces of baked gauze secured in position by corrosive collodion. Over this the powdered boric acid and iodoform are thickly dusted. Then a thick pad of baked gauze is placed on the lower abdomen and pubes. The whole is kept in place by an abdominal binder, or adhesive plaster, and perineal straps. The patient is kept in bed two weeks. At the end of a week the sutures are removed, and the lines of incision are covered with powdered boric acid and iodoform, and sealed over with baked gauze held in place by corrosive collodion. If possible the catheter is dispensed with and the nurse is instructed to see that the patient passes her water every four or five hours. The moment any bladder trouble shows itself, saccharine, boric acid, and benzoate of ammonia are given. The bowels are moved on the third day by a large dose of magnesia, assisted by enema, so as to avoid straining. After this the bowels are moved every day. Slop diet is given until after the third day. If suppuration appears, a large opening is at once made down to the ligament; at times it is necessary to open up the whole incision. Then poultices are applied for twenty-four to thirty-six hours, then the suppurating cavity is cleaned two or three times a day with peroxide of hydrogen and filled with powdered dermatol, aristol, or iodoform. The occurrence of suppuration does not prolong the patient's stay in bed.

The following cases were operated on at the St. Elizabeth's and Carney Hospitals, Boston, during the two years following December, 1889:

TABULATED STATEMENT OF CASES ON WHICH THE ALEXANDER-ADAMS OPERATION WAS PERFORMED IN THE ST. ELIZABETH'S AND CARNEY HOSPITALS, BOSTON (1889-1891).

Number.	Date.	Name.	Age.	Married.	Single.	Children.	Abortions.	Indication for operation.	Operator.	Other operations.	Relief of symptoms.	Results.	Remarks.
1	Dec., '89...	A. H.	22		S.			Retroversion.	J.	Dilated; curetted.	Yes.	Perfect.	
2	Jan., '90...	M. C.	24		S.	..		Retroversion; prolapsed ovaries.	C.	....	....	Perfect.	
3	Feb., '90...	R. N.	25	M.	..	..	..	Retroversion.	J.	Cervix.	Yes.	Perfect.	Pessary for a few months.
4	April, '90 ..	H. C.	27	M.		2		Retroflexion; prolapsed ovaries.	J.	Cervix; perineum.	Yes.	Perfect.	
5	May, '90...	K. D.	18	..	S.	..		Retroversion with adhesions.	J.	....	No.	Perfect.	Pessary for a few months.

F. W. Johnson.

ALVELOS. The milky, resinous juice of Euphorbia heterodoxa, Müller, belonging to the order Euphorbiaceæ, indigenous to Brazil. It is obtained by expression, is yellowish-white, of syrupy consistence, resembling vaseline, insoluble in water and alcohol, soluble in ether, miscible with fixed oils.

It possesses powerful escharotic properties, together with a solvent action on organic tissues. It combines the effects of a caustic with that of papaine. It is recommended for the treatment of syphilitic and cancerous growths. The part is painted with the drug once a day; before the application the part is washed with carbolic acid or other antiseptic solution. The operation is repeated until the disease is removed. It is said the purity of the drug may be known by its imparting a pronounced color and odor to the urine due to its absorption. This effect has to be watched during its use as it exerts a decided irritant action in the renal tissue. *Beaumont Small.*

AMPUTATION AT THE HIP-JOINT. The mortality which until recently followed amputation at the hip-joint rendered this operation the most formidable in surgery. Within the last ten years this mortality has been greatly reduced. No great war has occurred within these years, so that it is difficult to estimate the present death-rate of traumatic cases. The reduction for such cases ought, however, to be proportionate with that of amputation for disease. For this latter class of cases, a dozen years ago, the mortality was estimated at over forty per cent. Now it varies from fifteen to twenty per cent. Formerly it was only on comparatively robust patients that the operation was performed; now it can be done on delicate, sickly children with a fair chance of a successful issue. The reasons for these better results are, 1st, the antiseptic treatment of the wound; and 2d, the improved methods for the control of hemorrhage. The first cause has brought about an immense improvement in all operations, and the improvement is in almost direct proportion to the extent of the wound, and therefore the difference between the present results and those of the pre-antiseptic times is more marked in this operation than perhaps in any other. The second cause has very much added to the safety of the operation. It cannot be said that any one method is pre-eminent for the control of hemorrhage, but there are several admirable plans for the arrest of bleeding, which, in different hands, give almost equally good results. Shock continues to be the source of the greatest danger, but this has been very much lessened since the loss of blood has been diminished. Following the removal of so large a part of the human frame, there must always result considerable shock. In this connection it is well to correct an erroneous statement which has been handed down from text-book to text-book for scores of years. It is very commonly stated that amputation at the hip-joint removes about one-fourth of the body. This is incorrect. Recent observations estimate the loss of tissue as equal to about one-tenth or one-twelfth of the weight of the entire body.

Methods. More than forty-five methods of amputation at this point have been described. Many of them are entirely obsolete. A very judicious choice has been made of the best methods in the original article on this subject, in Vol. I. Of the plans there described, several continue to be used with great success. The shape and position of the flaps are of less importance than the means for control of hemorrhage. In many patients the flaps must be adapted to each case, and especially is this true in amputations for injury. Some modification of the method known as Furneaux Jordan's is perhaps as generally useful as any other. The flaps are formed as follows: the soft parts are drawn upward with the left hand and a circular incision is made through skin and cellular tissue around the middle third of the thigh. The cuff of skin is raised for about two and a half inches, and this flap being drawn strongly upward, the muscles are severed by circular sweeps of the knife down to the bone. The vessels are then secured. A second incision is made along the outer side of the thigh, starting from the circular wound and ending midway between the iliac crest and the top of the great trochanter. This incision divides everything down to the bone. The soft parts are then peeled off the femur, and the head of the bone disarticulated. If the case is not suitable for this method an equally good stump can be obtained by one of the other methods.

Means of Arresting Hemorrhage.—While several new devices for this purpose have been introduced, yet some of the older methods still give very satisfactory results; of these may be mentioned control by means of the elastic bandage, according to the plan of Jordan Lloyd. In this method the Esmarch bandage is first applied, as far up the thigh as the tissues are healthy; a piece of strong rubber bandage is then passed between the thigh and trunk, its centre resting between the anus and tuberosity of ischium. A roller bandage is placed over the external iliac artery. The ends of the rubber bandage are drawn strongly upward and outward, one in front of the groin, and the other across the buttock, to a point above the crest of the ilium. They should be pulled until all pulsation in the femoral artery has ceased. The anterior band compresses by means of the roller bandage the external iliac, and the posterior the branches of the internal iliac artery. The ends of the bandage can either be held by an assistant, or crossed over to the opposite side and tied below the crest of the ilium. Another plan, which in the hands of its inventor, and of others, gives excellent results, is Davy's rectal lever. Ten cases have recently been reported treated by Davy, with eight recoveries. Trendelenburg's method of passing a steel rod between the vessels and femur, and

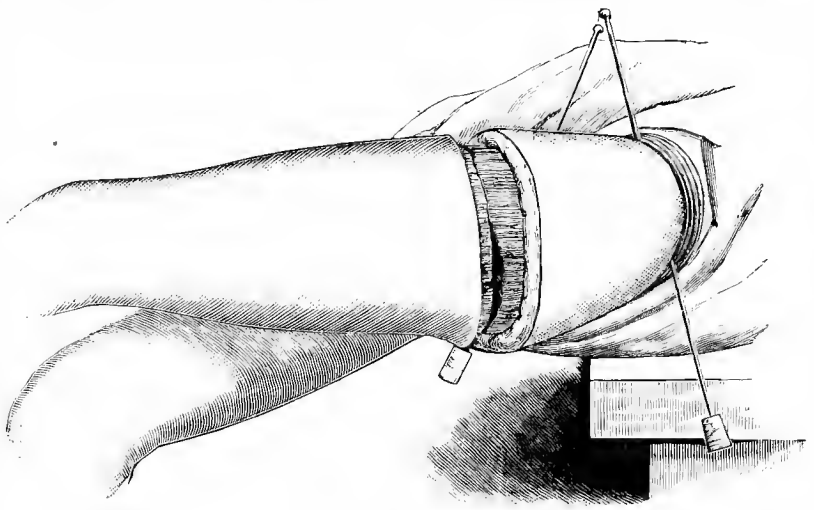

Fig. 15.

compressing the artery by a rubber cord, is also a very serviceable device. The most satisfactory method is the one recently proposed by Dr. Wyeth. The patient is placed with the hip well over the end of the table, and an Esmarch bandage applied. With the bandage still in position, his needles are inserted as follows: "Two steel mattress-needles, three-sixteenths of an inch in diameter and a foot long, are used. The point of one is inserted an inch and a half below the anterior superior spine of the ilium and slightly to the inner side of this prominence, and is made to traverse the muscles and deep fascia, passing about half-way between the great trochanter and the iliac spine, external to the neck of the femur and through the substance of the tensor vaginæ femoris, coming out just back of the trochanter. About four inches of the needle should be concealed by the tissues. The point of the second needle is entered an inch below the level of the crotch, internally to the saphenous opening, and passing through the adductors, comes out about an inch and a half in front of the tuber ischii. No vessels are endangered by these needles. The points are protected by corks to prevent injuries to the operator's hands. A piece of strong white rubber tube, half an inch in diameter, and long enough when tightened in position to go five or six times around the thigh, is now wound very tightly around and above the fixation-needles and

tied." The Esmarch bandage is then removed, and if the operation is to be completed according to Dr. Wyeth's plan, a circular incision is made, the skin-flap is turned up, the muscles are divided at the lesser trochanter, and the bone is sawn through. All vessels are then tied. The remaining portion of the femur is then removed by division of the attachments of the muscles. It is not, however, necessary to complete the operation in this manner. In one of my cases Wyeth's pins were applied and the flaps were formed according to Farneaux Jordan's method, and the bone disarticulated while the pins and tubing were still in position, and before a vessel had been secured. The arrest of hemorrhage was perfect, and not a drop of blood escaped from the upper ends of the cut vessels. I should add that in this case a roller bandage was placed over the iliac artery, but I do not know that it was necessary, as in another case no such compression was used, and no leakage occurred from the vessels. In both patients the complete arrest of hemorrhage was highly satisfactory, as has over and over again been testified to by the inventor of this admirable method, and by others who have made use of it.

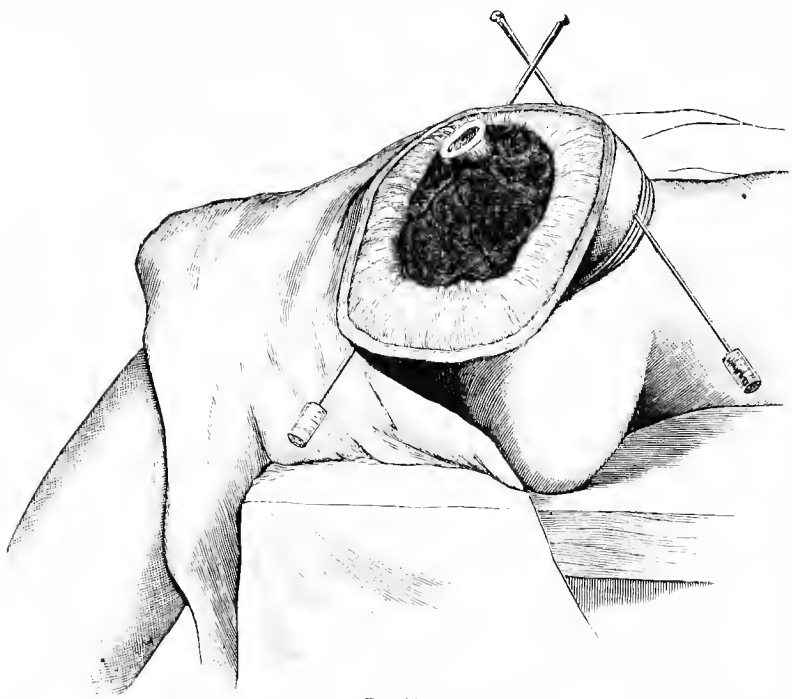

Fig. 15.

The accompanying diagrams, inserted with Dr. Wyeth's permission, illustrate the method of the introduction of the pins.

In one of my cases, a very large man, I found that needles fifteen inches long were more serviceable than would have been the shorter ones.*

Whatever method be adopted, the wound should be closed by suture and two or more drainage-tubes inserted. The entire operation should be carried out with the strictest antiseptic precautions. It is important that the patient should be enveloped in flannel, and that the room should be thoroughly warm. It is also useful, in weak patients, to adopt a modified Trendelenburg's position, with the pelvis elevated and the head low.

Andrew J. McCosh.

AMYLENE HYDRATE (*Dimethyl ethyl carbinol*). This is a clear, colorless, thin, neutral liquid, with a burning taste and an aromatic odor somewhat resembling camphor. It is soluble in eight parts of water and in alcohol, ether, glycerine, and oils; specific gravity .815. Recommended in 1888 by Professors Jolly and von Mering for its soporific properties. It is said to occupy a place between chloral and paraldehyde, two parts equalling one of the former and three of the latter. Its advantage over chloral is that it has no depressing effect on the heart; its smaller dose and less disagreeable odor make it preferable to paraldehyde in many cases. It produces a calm refreshing sleep, which lasts for six or eight hours, from which the patient awakens without any bad symptoms. It is used in insomnia due to nervousness, debility, mental excitement, and delirium tremens, and in fevers. It has not proved of much use when the sleeplessness is due to pain. It does not cause headache, nausea, or deranged digestion. In very large doses it produces a lowered temperature, shallow respiration, feeble pulse, loss of reflexes, paralysis of extremities. It is given in doses of thirty to forty-five minims. Its taste and odor often prove objectionable, and may be disguised by combining with extract of licorice, or some aromatic. It may also be used as an enema with mucilage of acacia, in doses of forty to ninety minims.

Beaumont Small.

ANÆSTHETICS. The period which has elapsed since the publication of the first volume of this work shows no addition of value to our agents for the production of general anæsthesia, no change in the principles which govern the process, nor has there been any decided change in the relative standing of the agents employed. Yet it has been a period of marked activity. The leading societies of the world have debated the subject, many papers of value have been published, while experimental study has been prosecuted to a degree greater than ever before. Few conclusions, however, have been reached which are universally accepted. On the contrary, there is wide diversity of views upon some of the most important points. Even experimental investigators have not agreed, and practical men have reached conclusions diametrically opposite.

The major part of the work done upon this subject during the last decade has had its origin in the contest between chloroform and ether. This contest, which began in the early years of anæsthesia, still continues, and without promise of early settlement. The advantages of each agent have been presented and urged sometimes with more warmth than judgment, and in more of a partisan than a scientific spirit. It needs but a glance through the literature of the period to show that this contest has been the inspiration of the work done, and that a record of the efforts of the advocates of the two great anæsthetics is a record of the progress of the subject.

A strong plea for chloroform has been made by Dr. Lombe Atthill, of Dublin.[1] At a debate held by the Medico-Chirurgical Society of Glasgow the weight of testimony was altogether on the side of this agent, both in the number of speakers and the amount of experience. Several men of high repute spoke in its favor. Dr. Hartley, of Leeds, stood almost alone as an advocate of ether.[2] In this country Dr. Chisholm has advocated chloroform as the best anæsthetic,[3] and Dr. Farrington has made a plea for it.[4] The claims of ether have been presented in valuable papers by Comte, by Julliard,[5] and

* The needles can be obtained from any large upholstering establishment.

by Fueter, of Switzerland,[6] and by Dr. Teale in the address on surgery before the British Medical Association in 1889, by Silex, of the Augenklinik of Berlin, based on two thousand five hundred administrations per annum,[7] and by Ormsby.[8] In this country ether has been advocated by Knapp,[4] an excellent and much-needed paper on administration has been published by Shrady,[9] and one on the time and amount of ether required to produce anæsthesia by Lovett.[10] Wood's address before the International Congress at Berlin, 1890, must be also considered as a plea for this agent.

The use of various mixtures of anæsthetics may be said to be on the increase. The administration of nitrous oxide first and then ether is confined to hospital practice from the necessity for complicated apparatus. It is resorted to a good deal in London. The plan of administering ether first and chloroform afterward, or *vice versa*, is followed to some extent in Europe, but statistics are wanting, as they also are as to several mixtures much used in Vienna. The A. C. E. mixture, which consists of alcohol one part, chloroform two parts, ether three parts, by measure, seems alone to deserve consideration. This preparation has certainly advanced very much in favor during the past few years. The increasing number of deaths from chloroform in England has excited alarm, and the A. C. E. has been chosen by those who would avoid the dangers of chloroform on one hand and the practical disadvantages of ether on the other. As preferable to chloroform, this mixture has had the powerful advocacy of the London *Lancet*, its merits have been recognized by Eastes,[10a] and the more recent authorities advise its use under many circumstances, as do Buxton,[11] and Hewitt, the author of the chapter on anæsthetics in "Treve's Operative Surgery." The experience of a lifetime with this mixture has been presented in a paper before the Ohio State Medical Society,[12] and the debate elicited upon it showed a very considerable use of it through at least one section of this country.

The attempt to determine the relative safety or danger of the different anæsthetics by statistics has continued, but without greater success than in the past. The factors cannot all be given. All deaths are not reported. In a single city the coroner investigated fifteen deaths from ether, only three of which had been reported.[13] No statement of the deaths from an anæsthetic in any city or country is of value in determining this question unless the number of administrations are also given. Again, the irregularity of occurrence of accident renders an immense array of numbers necessary. Thus, in the debate at Glasgow, while several speakers testified to many thousands of safe administrations of chloroform, one of the participants had met with four deaths. Bardeleben had no death in 30,000 administrations, then in one year he had four.[14] Kollock had two deaths from ether in giving it 200 times.[15] Richardson found in the records of eight hospitals 17,000 administrations of chloroform up to 1864, before there was a death; in the same hospitals during the five subsequent years there were six deaths in 7,500 administrations. Of two hospitals, under circumstances almost identical, there was in one 1,575 administrations without a death; in the other there occurred one death to every 525 administrations.[16]

The following statistics, taken from the records of institutions, may be accepted as accurate.

	Administrations.	Deaths.
Bristol Infirmary, seventeen years:[16a]		
Chloroform	5,902	3
Ether	704	1
St. Bartholomew's Hospital,[8a] 1878–87:		
Chloroform	12,368	10
Ether	5,509	2
Ether, preceded by NO_2	9,072	1

[Both the ether deaths were in patients very feeble from prolonged intestinal obstruction.]

Richardson,[16] 13 hospitals, 1848–69 inclusive:		
Chloroform	35,162	11

Recently, very large collections of administrations and deaths have been made, and are presumably reliable:

	Administrations.	Deaths.
Julliard:[8]		
Chloroform	524,507	161
Ether	314,738	21
Weir, New York Hospital:[9c]		
Ether	10,791	6
Gurlt[17] (XX. German Surgical Congress):		
Chloroform	22,656	6
Ether	470	0
Ether and Chloroform	1,055	0
Ether, Chloroform, and Alcohol	470	0
Gurlt[9b] (XXI. Congress, including above):		
Chloroform	94,123	36
Ether	8,431	1
Ether and Chloroform	2,891	1
Ether and Alcohol	1,380	0
Bromide ethyl	2,179	0

Gurlt presents the collective experience of German surgeons. The value of his first series is increased by stating the relative occurrence of dangerous symptoms, which was: Chloroform, 71; ether, 0; ether and chloroform, 5; ether, chloroform, and alcohol, 4. The latter mixture is not the A. C. E., but one in which the proportions are: Chloroform, 100 parts; alcohol and ether, each 30 parts.

By the study of such statistics the relative danger of the different anæsthetic agents may be approximatively reached. The latest German writer accepts the statistics of Andrews, of this country, which make the mortality for chloroform, 0.37, and ether, 0.04.[14] Wood gives the danger from chloroform as four or five times greater than that from ether,[13] and this agrees very nearly with the conclusion reached by all who have studied the subject statistically. Still, there are demurrers. A reviewer commenting upon the deaths reported in England, 1870–85, says that chloroform being used in so much larger a number of cases than ether, the deaths (chloroform, 184; ether, 28 deaths), do not show it to be the more dangerous agent. Macewen, commenting on like statistics, computes that chloroform is given in Great Britain ten times to ether once, and takes the same position.[2] Further, the advocates of chloroform maintain that deaths during the operation alone do not represent all the mortality from ether. They claim that this anæsthetic frequently causes death by inducing bronchial and pulmonary affections, especially in the old, and that such cases do not appear in the tables of comparative statistics. It must be admitted that the claim is just. Gerster saw three fatal cases of pneumonia after ether, and he reports two more and one serious attack. Five serious attacks of bronchitis followed the administration of ether in one institution.[9c]

Experiment upon animals as a means of determining the relative danger of the two great anæsthetics has been actively prosecuted during the last few years. The Hyderabad Commission (see under Chloroform) began this work. In the number and variety of experiments made, this commission surpassed all former efforts in this direction. But the observations they reported and the conclusions they arrived at differed so widely, so diametrically, from those of all other experimental physiologists that a revision and repetition of former work was absolutely necessary. The Commission, in their experiments, saw no deaths from failure of cardiac action. The conclusions they reached were: 1, That chloroform never causes death in dogs by affecting the heart; 2, that death always takes place by the respiratory organs and that disturbance of the function of respiration invariably gives warning of danger; 3, that when the action of the heart does fail it is the result of asphyxia, *i.e.*, of some interference with breathing, and is not a direct effect of the chloroform. These doctrines, but especially the application of these doctrines to the human subject, together with the deduction that safety could always be insured by the simple measure of watching the respiration, threat-

ened to revolutionize the clinical aspects of the subject. A number of experimental studies followed in rapid succession. Wood and Hare came first with a repetition of experiments and of new ones devised.[18] They arrived at the same conclusions as before, that chloroform is a powerful depressant poison, acting sometimes on the respiration, sometimes on cardiac action, and sometimes on both together; that it surely causes death by paralyzing the heart; that it sometimes does this at an early period of the administration when but a small quantity has been inhaled; and that the danger of cardiac arrest by this agent is in direct proportion to the concentration of the vapor and the rapidity of its administration.

Dr. MacWilliam reported to the British Medical Association an exceedingly interesting and important experimental study of the comparative effects of ether and chloroform.[1c] The results seem deserving of especial attention, because obtained by a method whereby the action of both ventricles and auricles were graphically recorded independent of, although with, tracings of the blood-pressure. Experiments showed, besides the usual fall of blood-pressure and marked diminution in force of the auricular and ventricular contractions, a decided dilatation of the organ. This dilatation was a constant feature; it affected all the cavities; they were imperfectly emptied. This change of form, too, was remarkable for the suddenness of its occurrence and the early period at which it occurred. It was often seen when but a small amount of chloroform had been given. Crucial experiments were made to determine that this change was not the result of changes in the systemic blood-pressure, nor effected through the vagi, and were not dependent upon asphyxia, or any interference with respiration, but that it was the direct effect of chloroform upon the heart itself. The conclusions were that "chloroform acts directly upon the heart, causes a marked depression of the cardiac muscle, a reduction of its tone, a relaxation of its walls, and an impairment of its functional activity." It was also proved that changes in the circulation frequently first gave warning of danger, and often before the respiration was affected. This had been clinically established before, but was denied by the Hyderabad Commission. A further important point of this report is the proof it gives that the rate and depth of respiration influence the effect of chloroform more than any other factor. By rapid or deep breathing an overdose may speedily be taken, and due dilution of the vapor with air is not, therefore, a guarantee against accident. The effect of ether upon the heart was concurrently studied by Dr. MacWilliam. It was shown to be in marked contrast with that of chloroform. Given less carefully and less gradually it caused but little change in the action or the form of the organ. Dilatation sometimes occurred, but then only in slight degree and when the ether was given in large amount and suddenly. As a rule it was absent and no effect upon the heart was manifested, while when chloroform was administered to the same animal in the same manner marked dilatation occurred and the force of the contractions was lessened.

Kappeler made a sphygmographic study of the various anæsthetics on patients and obtained results which correspond closely with those of Dr. MacWilliam, and which are more favorable to ether than those given in his work published in 1880.[19] He observed a noteworthy difference in the pulse-curves under ether and chloroform. The depression which always took place in greater or less degree with the latter, only occurred with the former in half the cases and then but in slight degree. With ether the curves showed any considerable change from the normal only when narcotism was pushed to complete abolition of reflex action and entire muscular relaxation. The observations showed that in its slight effect upon the pulse ether is an exception to all other anæsthetics. Yet in deep and prolonged administration similar changes occurred with both, so that "while death from syncope will occur less frequently under ether than under chloroform, such a death is, from the pulse-curve in ether narcosis, very possible."

All experiments, then, with the sole exception of those of the Hyderabad Commission, concur in supporting the conclusions reached by Wood, that "ether usually acts very much more powerfully upon the respiration than upon the circulation, but occasionally, and especially when the heart is feeble, ether is capable of acting as a cardiac paralysant, and may produce death by cardiac arrest at a time when the respirations are fully maintained; that chloroform is capable of causing death either by primarily arresting the respiration, or by primarily stopping the heart, but that commonly both respiratory and cardiac functions are abolished at or about the same time." Shore devised and executed a series of ingenious experiments wherein chloroform-carrying blood was restricted to the head of an animal, and in another to the body, the head receiving none. In the one case the fall of blood-pressure took place, in the other it did not; it was thereby proved that this fall was the effect of a direct action of chloroform on the heart and not on the vaso-motor centre.[1a]

By recent experimental study, then, we have gained much, but rather in confirmation of doctrines already accepted than in addition to our knowledge. The dilatation of the heart under chloroform, and the slight effect upon its action by ether had been observed by the first committee of the British Medical Association.[1c] But now an essential difference of action upon the heart by the two agents is accepted no longer as a matter of clinical deduction, but stands proved beyond question. The doctrine of Bernard, endorsed by the Hyderabad Commission, that ether and chloroform are similar in action and differ only in degree, is no longer tenable.

Notwithstanding the proof of an essential difference in mode of action between the two anæsthetics their relative standing has not much changed during the period under consideration. Chloroform still holds the leading position. Ether has gained considerably in England and still more in Switzerland. It has not made any advance in France; there, "chloroform reigns almost without a rival."[20] The A. C. E. mixture has advanced in favor, and is now largely used, especially in some sections of this country and in England. The estimate given at the Glasgow debate was that chloroform is given in Great Britain ten times to ether once. The statistics of the Twentieth German Surgical Congress showed 22,656 administrations of chloroform and 1,472 of mixtures to only 470 of ether.[14] The second series of Gurlt's statistics shows a great advance of ether. Chloroform is, then, still the leading anæsthetic of the world, despite its greater danger, proved by experiment and deduced from clinical experience.

The tendency of the practice of the present time is to a choice of anæsthetic, rather than to the banishment of either. The doctrine is gaining ground that each agent is better adapted to certain cases than the other, and that it is the duty of the surgeon to choose the anæsthetic according to the patient or to the operation to be performed. In this country Gerster and Hunter McGuire have ably supported this course. Dastre likens the adhesion to either chloroform or ether alone to the attempt made in the Academy of Medicine in 1833 to determine whether the treatment of pneumonia should be by venesection or by cathartics.[21]

The operation may determine the choice. For operations upon the nose, mouth, and pharynx chloroform is the best, and especially when the actual cautery is to be used. Tooth-drawing is an exception, however. Nearly ten per cent. of deaths under chloroform have occurred in dental practice, a proportion enormously high when the relative number of administrations for other purposes is considered. Nance says that chloroform should never, upon any consideration, be given for the extraction of teeth.[8b] Dastre emphasizes the different effect of the two agents upon the capillary circulation, chloroform restricting, ether increasing it. For operations after which much capillary hemorrhage may be expected he would therefore prefer the former. For protracted operations testimony differs as to which is the safer agent. The preceding administration of morphine, or morphine with atropine, by subcutaneous injection, best

promotes the prolongation of anæsthesia with a minimum of the agent. As to operations the success of which may be prevented by vomiting, there is a singular discrepancy of testimony. Thomas has seen such bad effects from this symptom after ether given for laparotomy that he thinks its abandonment for such cases worthy of serious consideration.[22] Cameron had the same experience in two out of four Cæsarean sections and would not use ether again in that operation.[2] On the contrary, one of the speakers at the same debate maintained that there was much less vomiting after ether than chloroform, an opinion also expressed by Zweifel.[7a] The influence of morphine and atropine is undoubtedly the best means of preventing vomiting and securing quiet after operations. Dastre is strongly in favor of this plan, supporting his opinion by the practical experience of Aubert of Lyons, and by citing the well-known influence of atropine upon the action of morphine as first shown by Brown-Séquard. So far as the experience of the writer goes it has not furnished a single case of severe vomiting after laparotomy for which anæsthesia had been effected by the A. C. E. mixture preceded by an injection of morphine and atropine.

Certain surrounding conditions may determine the anæsthetic. Artificial light, if in open flame, would banish ether on account of the inflammability of its vapor. Both McGuire and Gerster would prefer ether, and justly so, when obliged to entrust the anæsthetic to an unskilled assistant. The limits of safety are more easily passed through inattention, carelessness, or want of skill, with chloroform than with ether. When the patient cannot be fully anæsthetized with ether of course chloroform should be given. Gerster found 11 such cases in 125 administrations.

The state of the patient has an important bearing upon the choice of the anæsthetic. During pregnancy the injurious effect of coughing and vomiting should be considered. Hewitt makes obesity a contra-indication to ether.[23] Arterial sclerosis should also forbid ether on account of the greater increase of blood-pressure under this agent. Dr. Agnew's fatal case is an instructive example. Atheroma is also, for the same reason, a contra-indication to nitrous oxide.[13] When the patient is very feeble, or has suffered from severe hemorrhage, or when shock is present, ether should be preferred. The opinion prevails that chloroform is the safer anæsthetic for the extremes of age. For the old this is correct, on account of the liability of the aged to diseases of the respiratory organs. That chloroform is especially safe with young children is open to the gravest doubts. No precise statistics can be given, but numerous deaths have occurred while the number of administrations is comparatively small. Of 67 deaths reported in *The Lancet*, 1880–90 inclusive, more than twenty per cent. were of children under fifteen; some three, four, and five years old. Chloroform is better for young subjects on account of its manageability and promptness of effect, while its vapor is far less unpleasant and less irritating than that of ether; that it is safer remains unproven. There is great unanimity of opinion as to the administration of anæsthetics to patients suffering from heart disease. Valvular disease, compensation being maintained, is no bar to their administration. Fatty degeneration, if diagnosed, would contra-indicate chloroform. Richardson says he knows of but one condition of exceptional danger with chloroform, "a dilated and weakened right heart."[16] There is no question that a patient with valvular disease will go through the strain of an operation or of a severe labor better with an anæsthetic, even with chloroform, than without. The autopsies of deaths under chloroform have not revealed lesions of the valves. McGuire has given chloroform to "hundreds of cases" of valvular disease without accident.[24] For patients with a "nervously weak heart," feeble in action from fear, he and some others would reject chloroform. The effect of morphine and atropine is best adapted to this condition, quieting the emotional element, which has sometimes alone been the source of danger and death. There is like unanimity of opinion as to disease of the respiratory organs. Here chloroform should be preferred. Hyperæmia of the larynx, bronchitis, and pneumonia, or a tendency to these diseases, forbid the use of ether. Pleuritic effusions add very much to the dangers. Three cases of death from ether in patients with empyema were reported at one society.[9] In some cases, as of emphysema with enlarged heart, judgment is difficult; there is danger on either hand. Here, as in many other cases, Buxton and Hewitt advise the A. C. E. Disease of the kidneys has been held to be a contra-indication to ether since Emmet, in 1872, first called attention to the subject. In recent years, however, the injurious effect of ether in patients thus affected has not only been questioned but denied, and at present very considerable difference of opinion prevails. Fueter reports a series of experiments with results wholly negative. He reports also four cases of patients with albuminuria to whom ether was administered without increase of albumin afterward.[6] Weir also reports five cases of patients who presented evidence of diseased kidneys before operation and without injurious effect.[4a] Buxton says that a considerable experience with operations on the kidneys in which he had given ether, induces him to attach less importance to this point than formerly.[1a] This is negative testimony. Looking over the positive evidence, such as that presented by Carpenter,[9d] the number of cases in which nephritis followed the administration of ether, those of death under ether in which the autopsy showed diseased kidneys, and it must be conceded that the weight of testimony sustains the view that ether exerts an unfavorable influence upon the kidneys and should not be given when they are diseased. To support this proposition Weir's statement may be quoted, that he found nine cases of transitory albuminuria after thirty-four administrations of ether.

Various measures have always been resorted to before inducing anæsthesia to modify the process, and with a view of lessening its dangers. The one most generally used, and in which the utmost confidence has been expressed, is a dose of some alcoholic stimulant. Clinical proof of the inefficiency of this measure is abundant. In about five per cent. of the deaths from chloroform this plan was followed. Since both Wood and McGuire have recently expressed the opinion that the influence of alcohol rather increases than lessens the danger from chloroform this plan will probably be abandoned. The sole excuse for resort to it would be great fear on the part of the patient, and this condition is much better met by the influence of narcotics. This latter modification of the anæsthesia is the most important measure of the kind. The method consists in giving hypodermatically $\frac{1}{6}$ to $\frac{1}{4}$ grain of morphine (0.0108 to 0.0162), and from $\frac{1}{150}$ to $\frac{1}{120}$ grain of atropine (0.0004 to 0.0005) about fifteen minutes before the administration of the anæsthetic. Much additional testimony in favor of this "mixed anæsthesia," or "mixed narcosis," has been recently given. A paper has been published in this country advocating it and presenting its especial advantages in gynecological practice.[25] Dastre has warmly advocated it, and given both physiological and clinical evidence in support of it. His testimony is very strong: "With chloroform alone we lost one dog out of three, and often had dangerous symptoms in the other two. During ten years with the mixed method I have not seen a single one die." Dastre supports the method in the human subject theoretically by claiming that "it is equivalent to a section of the vagi;" that "all arrests of cardiac action under chloroform are certainly active, not paralytic; they are due to the action of the pneumogastric nerve, and may be prevented by the suppression of the activity of this nerve." However this may be, sound physiological support of the measure is to be found in the stimulating influence of atropine on respiration and cardiac action, as first shown by Harley and by Bartholow. Dastre presents a large amount of favorable clinical evidence from the surgeons of Lyons, where the practice has been followed for eight years, and in "several thousand cases" without accident. The plan is advised and followed by Buxton and McGuire. Pozzi[20] says that to this method "can scarcely be awarded too much praise in operations of any considerable length. . . . It pre-

vents the initial excitement, diminishes the nausea, limits the amount of chloroform used, and consequently lessens the chances of chloroform-poisoning in operations of long duration."* The changes, then, which have occurred in this branch of artificial anæsthesia in the past few years may be said to be: 1. The presentation of a large amount of evidence, both experimental and clinical, in favor of its greater safety. 2. An increase of evidence as to its influence in lessening vomiting. 3. The great probability that the benefits of the measure are not restricted to chloroform. Kappeler[26] had given his opinion against the administration of narcotics before ether, believing that they increased the danger. Experience has not sustained this. Julliard gives morphine and atropine before ether. The writer has used them before the A. C. E. during a lifetime, and has not once seen dangerous symptoms. Shrady advises morphine before ether in drinkers. The latter writer also presents strong testimony as to great economy of anæsthetic and of time by this method. Plastic operations under ether which required one hour were performed in half that time when morphine was given first.[9] Adverse opinion has been expressed upon this method; adverse testimony, however, is not strong. The Hyderabad Commission is not favorable to atropine, but advises the use of small doses of morphine under some circumstances. Macewen states that "the action of morphine becomes intensified in the presence of chloroform." Yet there has been such an amount of clinical experience with this method that if it added to the danger the fact would be apparent. Some deaths have been reported;[26] one recently in this country after the administration of a quarter of a grain of morphine,[46] preceding chloroform.

Two points in regard to anæsthesia may be considered settled: 1. There is no especial mode of death under either anæsthetic; that ether always causes death by the respiration, and chloroform always by the heart, is no longer tenable. Wood's statement (*v. ante*) gives our present knowledge as to modes of death and their relative frequency. 2. All anæsthetics are dangerous; no care, no precaution, no particular apparatus or method of administration insures absolute safety. This is the expression of all recent authorities, the Hyderabad Commission alone excepted.

In measures for resuscitation of patients in danger from anæsthetics some changes have taken place. The beneficial effect of galvanism remains unproven. Two remedies generally resorted to have been shown by Wood to be not only useless but injurious; they are the administration of ether and of alcohol. Unsupported by reason, experiment shows that they should be abandoned. Digitalis, given hypodermically, exercises a marked influence upon the circulation, and Wood saw, several times, the death of animals averted by it. Strychnine also produces a marked stimulating effect upon the respiration with a rise of blood-pressure;[13] but Reichert's experimental studies do not sustain Wood's opinion of the value of strychnine as a respiratory stimulant.[27] Hankel recommends it, however, "as the strongest stimulant of the respiratory centre and of the motor cardiac nerves." As to nitrite of amyl, the testimony is conflicting. Wood found its effect negative. Buxton says it is not a physiological antidote to chloroform. On the other hand, Shrady and others report having used it with benefit, and Burrall has published a paper with a collection of cases in its support.[9c] Inversion of the body scarcely holds the confidence it once had. The existence of cerebral anæmia, upon which this measure is theoretically based, is doubted by Wood. Dastre says that ether causes cerebral hyperæmia, and that therefore, with this agent, the dependent position of the head is likely to aggravate the symptoms. The measure originated from observation of its good effect on animals, and experiment still sustains it. Wood saw its good effect frequently, and in some cases repeated so often that it could not be attributed to accident. There is very strong clinical evidence in its favor. Chisholm has reported cases of recovery quite as striking as the one first described by Sims in Nélaton's practice. He gives four successful cases; in one the measure was repeated three times before the completion of the operation.[9c] Artificial respiration still maintains the leading position it has always held. Authorities are unanimous as to the superiority of this measure. It has the strongest support from experiment. In man, if respiration be in abeyance, this is the direct and only way to restore it. If the heart is paralyzed nothing can restore its vitality, but its action may be so reduced as to be imperceptible, and then the manipulation of the chest-walls is an effective means of increasing it. Early resort to it is important. The Hyderabad Commission found it successful almost without exception if not more than thirty seconds had elapsed before it was commenced, and almost useless if not begun until after fifty seconds. Nussbaum emphasized the importance of the first minute. Whatever method be followed thorough expiration should be first effected. By this means the anæsthetic vapor of the residual air is expelled. Again, expiration is much more affected by anæsthetics than inspiration.[21] In deep anæsthesia expiration is purely passive, very feeble, and danger to respiration comes in this way. Nussbaum's plan was, thorough slow compression of the thorax and abdomen with both hands, and this repeated every three or four seconds. He had 15,000 administrations of chloroform without a death; nine times, however, the escape was narrow, and once ten minutes elapsed before the first breath was drawn, and thirteen more before respiration was established.[14] König's plan is similar; it consists in compression of the cardiac region, repeated thirty to fifty times in the minute, one thumb pushing deeply into the space between the ribs and left edge of the sternum. Maas reports two striking recoveries by this method.[7b] The patients were nine and a half and thirteen years old; both were pulseless, with suspended respiration and dilated pupils; in one artificial respiration by Sylvester's method and inversion of the body was tried; in both there was opportunity to observe the good effects of the measure several times, and over an hour of perseverance was required before recovery was assured. McWilliam found that the most powerful way of increasing the carotid blood-pressure in animals deeply narcotised by chloroform was by firm intermittent compression of the abdomen.[15]

Considerable attention has been directed of late to the purity of chloroform. Probably very few, if any, deaths have been caused by an impure article. Dastre found no instance in 132 fatal cases which occurred from 1865 to 1880, and he thinks this a convenient explanation of death for the relief of the administrator. Recently, however, DuBois-Reymond has made a study of this subject. He has followed a plan devised by Pictet, of Geneva, whereby chloroform is submitted to the influence of intense cold and impurities in it thus removed. Chloroform thus purified showed far greater stability;[27] exposed to air and light it remained unchanged for a week, while ordinary chloroform showed signs of decomposition within two days, sometimes in a few hours. Anæsthesia was produced by the purified article more promptly and was more enduring. Experiments were made on animals with the residue and the injurious effect of the impurities thus demonstrated.[28] In Germany, according to Foy,[29] great impurity of chloroform is not rare. In England chloroform is likely to be contaminated with the methyl compounds from the use of methylated spirit in its manufacture.[8c] Reynier found necessity for investigating the purity of chloroform in France.[30] He attributes cough, vomiting, bronchial hypersecretion and arrest of respiration to impure chloroform. He had observed a far less mortality in dogs experimented on since he had used only chloroform rectified the evening before and kept in colored bottles. In the debate M. Lucas-Championnière maintained the importance of this point; with pure chloroform anæsthesia is regular; with impure there are irregularities

* This writer claims it as "the method of Dastre and Morat." It was used in this country from 1870, continuously since, and publicly advocated as early as 1876.[25] Dastre's work appeared in 1890.

and accidents. In obstetrical practice he had found it of especial importance. "If I have good chloroform I effect readily that demi-anæsthesia desired in natural labor; if not, I fail; I narcotise too much or not enough." DuBois-Reymond's chemical position has been called in question by Schacht.[21] In this country pure chloroform, the product of reliable manufacturers, is everywhere at command, yet the necessity of care in selection is shown by the following official table of examinations of the articles:[31]

		Number of examinations.	Good quality.	Fair.	Inferior.	Not ether at all.
1889.	Chloroform	21	15	5	1	..
	Ether	68	40	4	22	2
1890.	Chloroform	13	8	4	1	..
	Ether	30	17	..	12	1
1891.	Chloroform	17	15	1	1	..
	Ether	61	38	4	19	..

The vapor of chloroform undergoes decomposition when exposed to the flame of artificial lights. Zweifel first called attention to this fact in a paper on pneumonia after laparotomy from decomposition of chloroform in gas-light.[7c] He maintained that gases are formed which are very irritating to the respiratory organs, occasion cough, and may be the cause of inflammatory affections. By the contrast of daylight operations and of those conducted under ether he furnished abundant clinical proof. Basshard studied the subject chemically and demonstrated that free chlorine and phosgene gas are formed when chloroform is exposed to gas-light.[18c] Eisenlohr and Fermi furnished experimental proof that injurious and dangerous gases may be thus generated.[17b] Amidon read a paper upon the subject which called forth reports of other cases from New York surgeons.[4c]

Fatty degeneration of the tissues is occasioned by prolonged and repeated inhalation of chloroform. The fact was noticed by Nothnagel in 1866. Attention was directed to it again by Unger in 1887, and his observations have been confirmed by Strassman and by Ostertag.[8d] The experiments of these observers showed that in animals exposed to prolonged inhalation of chloroform the internal organs had undergone fatty degeneration; that certain individuals exhibited a greater susceptibility to this change than others; and that in these animals death took place by paralysis of the heart. The fact should be known as one having clinical possibilities.

Bichloride of methylene, introduced by Richardson in 1867, has not succeeded in gaining a footing in this country. Nor has it advanced in favor elsewhere, notwithstanding Wells's experience of twelve hundred administrations without a sign of danger. Pleas have recently been made in its favor by Day,[1d] and by Richardson,[16b] the latter giving a large, varied, and successful experience. Bichloride of methylene, pure, is a "convulsive anæsthetic," not adapted to surgical use. The liquid which passes under this name as methylene is a mixture of chloroform 10 parts and alcohol 30 parts.[21] Kappeler obtained several specimens from the best English sources and found them to consist of "a mixture of chloroform and methyl alcohol, with traces of chloromethyl."[19] Richardson does not claim that it is pure, but that "a less refined product answers even better for anæsthesia than the real CH_2Cl_2." The rate of mortality of this agent has been high. Kappeler refers to 14 deaths collected by himself in 1879, and gives 5 more. Hankel says that the few leading English journals, 1869–80, contain reports of 11 deaths from it, 7 by syncope. This was the same mortality as that from ether during the same period with a very far greater number of administrations. Dastre attempts to reconcile the high rate of mortality in general with Wells' and Richardson's successful experience. He believes an explanation may be found in the different temperatures at which the agent was administered, in changes which take place in the liquid even during administration, and especially in the use of Junker's inhaler, a closed apparatus, which influences both the other factors.

The bromide of ethyl seems to be actively recovering from the neglect into which it fell about a decade ago. The reaction began in 1888, and has been the work of German dentists. Strong testimony in its favor, experimental and clinical, was presented to the Tenth International Congress by Holländer and Abonyi. A paper embodying the experience of 1,500 administrations is given by Gilles.[7d] It is stated that there have been 20,000 safe administrations in Germany, the accidents being attributed to impurity of the article used. In this country it has been advocated by Montgomery, 500 cases, by Kuykendall, 250 cases,[27bis] and it is stated that Chisholm and Prince have administered it to several thousand cases.[27] It has been opposed by Mittenzweig, who gives three cases of poisoning in Berlin, two fatal.[1b] Brinton was led to abandon its use from unpleasant experience.[27] Dastre says: "If physiological analogies do not deceive us, the bromide of ethyl, for long operations, offers greater dangers than ether or chloroform." Kappeler found that it exercised a marked influence upon the pulse-curve, and hopes that it will be "consigned to forgetfulness."[19] The writer inhaled it three times, under the supervision of medical friends; its effect upon the pulse was so marked that he decided never to administer it.[32] To all previous adverse experience the friends of this agent urge that the purity of the article is essential; and it is an article very difficult to obtain pure. Nevertheless Witzel, who terms it "the safest narcotic for human beings," saw, in 465 administrations, disagreeable symptoms 28 times, asphyxia in a number of cases, and twice artificial respiration was required.[27c] Gilles urges the importance of a special technique: it should be given more freely than chloroform; the mask should consist of several folds of gauze, so as to carry considerable liquid, and over this should be an impermeable cover. Anæsthesia by this agent is exceedingly pleasant, very rapid, with equal rapidity of recovery. The writer can testify to these points from personal trial, and, if safe, he would term it the ideal anæsthetic. The time required for complete anæsthesia is fifteen to ninety seconds, average eighteen. The following points are derived from the writings of advocates as well as opponents: 1. Bromide of ethyl is adapted only to very short operations, those lasting not over a minute or two. 2. Not more than five to ten grammes should be administered. 3. Muscular relaxation is not obtained; a gag is necessary for tooth-extraction. 4. Muscular rigidity is frequent, sometimes tetanic, with opisthotonos. 5. Excitement, although unusual, is sometimes greater than with chloroform. 6. Dreams are extremely vivid and sometimes erotic. Gilles denies that they are of this character "in one-third of all cases." He saw sexual movements in one case, and Wetzel saw them in women several times in 465 administrations. 7. In some cases it is followed by distressing vomiting, even when but a small amount has been given. 8. Arterial hemorrhage is favored. 9. An unpleasant odor of garlic is present for some days in the breath of those who have inhaled it. In view of the conflicting experience, this agent should be submitted to further careful chemical and experimental investigation. The authors of the papers above quoted concur in the statement that neither pulse nor respiration are materially affected in patients submitted to its influence.

There has been no change worthy of note in either the theory or practice of anæsthesia in obstetrics. No addition to the mortality in natural labor, the anæsthetic being administered by a medical man, can be recorded. A brief treatise upon the subject has been published in this country as part of an obstetrical work.[33] Baldwin has made a plea for a more general resort to chloroform in labor,[12b] and Barker has published an inquiry as to the influence of anæsthetics in causing post-partum hemorrhage.[18b] This paper is based upon the observation of several thousand cases, and the author's conclusion is that chloroform, properly administered, need never be withheld on account of hemorrhage. The experience given in support of the doctrine that valvular disease of

the heart is no bar to the use of chloroform is especially valuable. Montgomery has advocated the use of bromide of ethyl in labor, and reported cases.[27c] The administration of this agent is restricted by its best friends to very brief periods. Charpentier presented the subject of anæsthetics in natural labor to the Obstetrical Society of Paris.[4a] He recognized the undoubted tendency of chloroform to diminish the contractile and retractile power of the uterus, and that in some cases it "has been the cause of more or less severe hemorrhage after labor." It is indicated "in primiparæ who are nervous and excitable, and in whom the pain may even cause delirium; in those in whom the labor is greatly prolonged; in all cases in which there is spasm, contraction, or rigidity of the neck or body of the uterus." It is contra-indicated in "absence of severe suffering, the existence of placenta prævia, general prostration, diseases of the circulatory or respiratory organs, cerebral disease, and alcoholism." In regard to cardiac disease, he is not in accord with Barker nor with the general testimony of authorities.

The occurrence of insanity after the administration of anæsthetics has been observed. This is the subject of a paper by Savage, read before the British Medical Association.[1c] Mental aberration has followed all the anæsthetics, as well as other deliriants, such as alcohol and belladonna. Such a result is rare, but its possibility may bear upon the use of these agents with patients having an hereditary disposition to insanity. One case with such disposition was related, in which insanity followed the first confinement, chloroform not having been given, while several times subsequently the anæsthetic was administered and no bad effect followed. Homans[10b] has reported two cases of insanity following ether, and several others are mentioned.[9] Papers upon insanity following operations, especially laparotomy, have been published by Baldy[15] and by Ill.[34] How far the mental disturbance in these cases should be attributed to the operation or to the anæsthetic it is impossible to determine.

Pental (*q. v.*) has recently been used in Germany as an anæsthetic for short operations, and several hundred administrations have been reported. As it caused cyanosis with absence of pulse and suspension of respiration in a healthy student, who submitted to its influence, as Gurlt reported to the Twenty-first German Surgical Congress one death in 215 administrations, and as Brewer, of Vienna, found measures of resuscitation necessary in one of every hundred administrations,[35] the future of this agent is not promising.

Local anæsthesia has been revolutionized within about a decade by the extension of the application of cocaine (*q. v.*). Menthol is also an efficient addition to our means of lessening sensation locally. The following, used with Richardson's spray apparatus, renders good service:

℞. Menthol..... gr. 2.5
Chloroform..... gr. 25.0
Ether..... gr. 37.50
M.

With the means now at command for local anæsthesia a death from chloroform, given for opening a mammary abscess,[36] could not be considered less than criminal.

[Since this article was prepared there has been published a large collection of statistics in the *Medical News*, October 29, 1892, and a valuable article on "Recent Physiological and Chemical Research on Anæsthesia" in the *British Medical Journal* of same date. A second edition of Buxton's work on Anæsthetics has also appeared, Philadelphia, 1892.]

ANCHYLOSIS. A new use of the terms *true* and *false* anchylosis, based upon the symptomatology and treatment, has recently been employed by a few orthopedic surgeons. They would have true anchylosis embrace both bony and fibrous union, provided it be complete, sound, and uninfluenced by use; false anchylosis would then be applied to those stiff joints in which some degree of motion is present, those in which disease (unsoundness) still remains, and all joints which by use become more deformed and more stiff, or less deformed and less stiff.

The justification of this terminology rests chiefly in the treatment. True anchylosis should only be subjected to treatment for the correction of existing deformity. *Brisement forcé*, osteoclasis, osteotomy, and excision are demanded, according to the nature of the deformity. False anchylosis, existing without deformity, should be treated by immobilization until the joint is quite sound; if the result is true anchylosis no further treatment is demanded; but if the joint recovers soundness with some degree of motion, the fullest possible restoration of function will be gained in time without further treatment. *Brisement forcé* and passive motion cannot be employed without a risk of rendering the joint once more unsound. If false anchylosis be present in a deformed joint, the deformity should be corrected under an anæsthetic, the surgeon using as much force as can safely be risked, at one or more sittings; after each forced correction the joint should be kept at rest until all pain has ceased, when the attempt to reduce the deformity should again be made. When the deformity has been fully corrected, the joint should be immobilized until it has become wholly sound, after which the rules applicable to a straight limb should govern the management of the case.

It is no longer believed that true anchylosis can be produced by immobilization alone, no matter how prolonged. The fact that anchylosis is present in a joint is a positive indication that it has been, or still is, the seat of some pathological process, and from this the logical conclusion follows that the treatment which will most rapidly cure the disease must result in the fewest cases of true anchylosis.

John Ridlon.

ANEMONINE. The active principle of *anemone pulsatilla, L.*, $C_{12}H_{12}O_6$. It crystallizes in needles, has an acrid taste, is slightly soluble in water, soluble in alcohol and chloroform. It is decomposed by alkalies.

It is recommended as a substitute for pulsatilla. Dose, from $\frac{1}{12}$ to $\frac{1}{2}$ grain. In large doses it is a powerful poison.

It is used in painful inflammatory affections of the ovaries and other pelvic organs, in orchitis and epididymitis, and in all other affections in which pulsatilla is indicated.

The alkaloid requires to be prepared with care, as the presence of anemonic acid converts it into anemone camphor, which produces its irritant and poisonous properties. *Beaumont Small.*

ANGEIO-NEUROTIC ŒDEMA. Definition: A vasomotor neurosis, characterized by the appearance of circumscribed swellings on various portions of the body, by preference the face, throat, and extremities, without apparent cause or premonition, and non-inflammatory in character.

Synonyms: Acute circumscribed œdema; acute idiopathic œdema; periodic swelling; urticaria tuberosa, or giant swelling; acute non-inflammatory œdema; Australian blight.

History.—Although references to this affection may be found here and there in medical literature since 1827, it is only within the past ten years that it has been recognized as a disease having sufficient individual characteristics to have a history and special designation of its own. It is to Quincke, and his pupil, Dinkelacker, that we are indebted for calling the attention of the profession to this disease, in such a lucid manner that it was at once recognized by other physicians.

Etiology.—*Age.*—The period of early life furnishes the greatest number of cases; the average age in a series of seventy-five cases examined by the author being twenty-seven. It rarely occurs for the first time in individuals upward of sixty years of age. Childhood, however, is by no means exempt; a case is reported by Dinkelacker, in which a child, whose father suffered from the disease, had an attack for the first time when it was three months old.

Sex.—It occurs nearly twice as often in males as in females, except in this country, where the proportion would seem to be reversed.

Occupation.—Those whose occupation tends to the production of excessive bodily and mental fatigue, are the only persons who show an increased susceptibility to the disease.

Heredity.—This is one of the most important and interesting elements in the genesis of the disease. It has been seen to run in families one generation after another. In a remarkable series, reported by Osler, the disease was demonstrated to be present in five generations, including in that time twenty individuals.

Previous and Present Condition of Bodily Health.—No relationship can be traced to previous, immediate, or remote disease, and the majority of the cases presenting themselves with this disease are in fairly good health.

Exciting Causes.—Of the directly exciting causes cold and traumatism are the most obvious. Others, such as fright, grief, anxiety, worry, and the ingestion of certain kinds of food, such as apples or fish, have all been found to be exciting causes in some patients. An attack is most commonly excited by cold, as in passing from a warm into a cold atmosphere, although it does result after severe muscular exercise with consequent sweating and then becoming cool very rapidly. The period in the twenty-four hours when attacks are most liable to show themselves, is during the time between 1 and 5 A.M., when the tide of life is at its lowest ebb, and the parts are least resistant.

Area of Distribution and Primary Point of Manifestation.—In a total of seventy-one cases the swelling showed itself for the first time: in the face, in twenty-nine cases; on the extremities, in twenty-two; in the larynx, in five; on the genitals, penis, and scrotum, in three; on the body, in six; on the gums and palate, in one; in the stomach, in three; on the neck, in one; and behind the ears, in one. Of the cases in which the swelling showed itself upon the face, three were restricted to the forehead; three occurred first on the eyelids; seven on the lips, and the remainder were distributed over various portions of the face. On the extremities the hands were by far the most often attacked, and after these the forearms were the next most frequent seat.

The occurrence of the swelling in one spot seems to predispose the place for future attacks, and it is the exception for it to be once seen in a place which thereafter remains free. Parts of the body which have received injury or have been the seat of protracted pain seem occasionally to be favorite places for the development of the swellings. Occasionally there seems to be a periodicity in the appearance of the swelling.

Symptomatology and Clinical Course.—The manifestations of the disease generally present themselves without warning, and the suddenness of their appearance and departure are rather characteristic. Possibly the patient may complain for a short time before the appearance of the swelling, of vague feelings of malaise, general disinclination to do anything, and a feeling of depression associated with ill-defined gastro-intestinal symptoms. The œdema comes on quickly, generally reaching its full development in a few hours, and gives the patient very little trouble, except by its mere presence; there is a feeling of stiffness and unwieldiness and a sensation as if the parts were on the stretch, but this sensation is not attended with pain or distressing throbbing, or any of the subjective symptoms of inflammatory swelling. The swelling is generally clearly circumscribed and plainly differentiated from the surrounding surface, and of a varying color. In some cases, but probably not in the majority of them, the skin is of a dark-red, dull roseate hue, while in others the marked contrast between the pale, almost waxy color of the swollen surface and the skin around it, is very striking. As has already been stated, the swellings have marked predilections for certain parts of the body. The œdematous part does not pit on pressure, or, if it does, only in a few cases, and in these not to any marked extent, so that the indentation produced by the forcible pressure of the finger is quickly effaced.

The subjective symptoms complained of by the patients are a sense of scalding or burning as the swelling is showing itself, these sensations being probably due to the marked tension under which the skin is suddenly placed; and after this, there is generally a feeling of itchiness. Outside of these, if the swelling does not encroach on any organ, such as the eye, the stomach, the penis and testicles, or does not block up the conductivity of a passage, as it sometimes does, and so produce trouble, there will be hardly any other subjective symptoms complained of. Frequently the surface temperature of the swollen part has been found to be slightly elevated, while on the other hand carefully made observations have demonstrated that the specific heat of these parts was considerably lowered. It is probable that at the beginning of an attack the surface temperature of the part is somewhat elevated, while later, or just before the swelling is going to wane, the temperature falls.

The swelling generally reaches its height in any one part in a few hours after its appearance, in some cases in a few minutes, while in others from six to eight hours will elapse. After remaining for a period varying from a few hours to as many days, it will begin to disappear, ordinarily with a rapidity corresponding to that with which it showed itself, and frequently its disappearance from one part is the signal for its appearance in another, which may have no anatomical or physiological relation to the part previously affected. As a rule it does not show itself in more than two or three localities at one visitation, and frequently only in one. The disease recurs, and in the analysis of the cases spoken of above, the time between the attacks averaged nineteen days. Occasionally a patient will have three or four attacks in a month, while others go for three and four months, and even longer, before they have a recurrence.

The symptoms of the disease when some of the mucous membranes are attacked are well marked and suggestive. As has already been said, the mucous surfaces most often attacked are those of the stomach and of the larynx. In about one-third of the cases gastro-intestinal symptoms are prominent. These symptoms are first a feeling of uneasiness and tension, as if something undigestible had been taken and had remained in the stomach. With this there is loss of appetite generally associated with constipation, which is soon followed by a distended appearance of the epigastrium; and then follows a sharp colicky pain,

often attended with profuse vomiting and great thirst. The pain is often so severe as to demand the administration of morphia. The character of the material vomited depends at first upon the contents of the stomach, but later on it becomes watery and somewhat stringy from the mucus which it contains, and frequently profuse in quantity. When this continues for any length of time the thirst becomes greater, and large quantities of urine are frequently passed, which, however, contains nothing abnormal with the exception of increased quantities of earthy phosphates. After this exacerbation in the symptoms has ceased, the reaction sets in, and there is frequently a diarrhœa of a colliquative nature, with an apparent retraction of the abdomen and a general feeling of lassitude and prostration, and the characteristic symptom of the disease shows itself in another part of the body, or, if it has already done so, it now begins to disappear.

When the swelling appears in the larynx it of course produces symptoms in proportion to the amount of encroachment that it makes. This is often so great that distressing symptoms of suffocation are produced, and, indeed, in some instances, in consequence of the œdema, death has taken place, and in many others the symptoms are so severe as to demand liberal scarification, or, more rarely, tracheotomy. As a rule the swelling does not pass by any continuity from the pharynx into the larynx, but when it is to attack the latter it shows itself with the same degree of abruptness and vigor there as in other parts of the body, and as a consequence the horrible sensation of choking to death is added to the patient's misery. Difficulty in swallowing when the seat of swelling is in the pharynx, is not so common as the corresponding symptom in the larynx, nor does it ever become so distressing. If it be granted that the œdema in question may manifest itself in the lungs, as many good observers would have us believe, the symptoms resulting will not differ materially from those of acute pulmonary œdema, except in the suddenness of its onset, the urgency of the symptoms, and the abrupt mode of departure.

Of the general health between the attacks but little is to be said. Generally there is nothing noticeably wrong; for a day or two after an attack there may be a slight feeling of prostration, especially if the gastric or intestinal mucous membrane has been attacked, but this soon passes away and the condition of the body is excellent until the next attack shows itself. Frequently there is not even this feeling of lassitude.

Diagnosis.—The diagnosis of a case of angeio-neurotic œdema will be attended with little or no difficulty if arrived at by the process of exclusion. The spontaneous appearance of the œdema, its recurrence at certain intervals, the absence of inflammatory symptoms, either local or constitutional, and the abruptness of its disappearance, are generally sufficient to enable us to recognize the disease at once.

It may be confounded with the blue œdema of hysteria, as described by Sydenham, or the white œdematous swellings occurring with the same disease, as described by Charcot. In hysteria, however, and especially if the hysterical attack is sufficiently profound to have œdema as one of its attendants, there will always be found the well-known stigmata which will be sufficient to make the diagnosis. Other factors, such as the abruptness of onset and the mode of departure, as well as the distribution of swelling in angeio-neurotic œdema, will corroborate the diagnosis.

There are a certain number of affections described under other names which are in all probability modified forms of this disease. They are, urticaria tuberosa, Australian blight, malarial œdema, etc. As will be seen at the beginning of this article these terms are considered as synonyms of the disease in question, and therefore require no further description.

Duration and Prognosis.—The duration of the disease varies from a period sufficient for one attack to a lifetime. The statistics bearing on prognosis do not allow us to draw conclusions that are of any great value on account of the fact that the patients do not often remain under the same physician's care sufficiently long to enable him to study the natural termination of the disease. From the evidence in our possession I am inclined to believe that the disease disappears after lasting a variable time, of from two to three years, in about one-half the instances. In the other half it may remain dormant for prolonged periods, but you can never prognosticate when or where it is next going to manifest itself. In others it continues to recur with varying intervals during the patient's entire life, which may not, however, be perceptibly shortened by the exhibition of these attacks. In some cases the manifestations cease to present themselves when the exciting cause can be obviated. It rarely causes death, and then almost alone by the involvement of the larynx and consequent suffocation. Whether or not the possession of this infirmity tends to shorten life by predisposing to other conditions which destroy the life of the patient, nothing definite has been observed, and there must necessarily be a greater number of observations before any justifiable conclusions could be drawn in regard to this point.

Pathology.—The pathology of the disease is as yet rather obscure. The nature of the lesion is unquestionably that of a non-inflammatory œdema circumscribed in form. The fact that the epidermis is not involved is an important corroborative fact, even if it was not so evident clinically that the œdema is in no way connected with an inflammatory condition. The seat of the œdema is probably most often in the connective tissue of the derma, beneath the papillæ, and in the subdermal tissue; very rarely the œdema confines itself to the more superficial parts. It is probable that although the lesions or the irritants on which the disease is dependent may attack the other parts of the system, yet the result directly appears through the sympathetic system of nerves. Furthermore, the nerves affected are undoubtedly the vaso-motor nerves. The disease in its development has a close relation to other vaso-motor neuroses, such as morbid blushing and flushing, exophthalmic goître, and to many of the arthropathies as yet not well understood. An œdema very similar to it is associated with tic douloureux, migraine, nerve-stretching, and the œdema occurring in hypnotizable subjects, following a séance.

Treatment.—Therapeutic measures are of little avail, either in mitigating the length or the severity of an attack, or in increasing the intervals between their occurrence. The greatest success will be obtained by adopting such measures as give tone and stability to the nervous system. As an all-round vaso-motor and general tonic to the nervous system of the body strychnia most nearly reaches the mark. It should be given in large doses and until its full physiological effects are manifest, particularly on the spinal cord; for although the affection is one indicating defect in the sympathetic nervous system, we must not forget that the origin of that system is in close relation genetically with the spinal cord. The next most important drug in the treatment is atropia; it should be likewise given in moderately large doses, and its administration continued during the intervals between the attacks. Tonics, invigorating baths, exercise, massage, and the prevention of trauma are the most important factors in the treatment of this disease. It is unnecessary to enter into details concerning the treatment for symptoms as they arise. If there be an excess of uric acid in the blood, as manifested by a disproportionate relation to the urea in the urine, this condition demands regulating. The same may be said of constipation, menstrual irregularities, and the like. The treatment at the time of an attack will depend somewhat on the part of the body where the disease is manifest. If the dermal surface of the body be involved, the most satisfactory plan of treatment is to keep the patient quiet, in an equable temperature, and apply dry heat to the swelling; and if there be much uneasiness or restlessness, a mild anodyne should be administered. Compression by means of a bandage or a Gamgee dressing is occasionally of benefit. When the disease manifests itself in the mucous membranes the treatment is entirely symptomatic. As has been before said, when the gastro-intestinal symptoms are prominent, morphia fulfils two conditions: it relieves the severe

pain and distention, and checks the vomiting for the time being. When the disease shows itself in the throat and larynx, it will occasionally be necessary to scarify and sometimes, but rarely, to perform the operation of laryngotomy. The use of electricity, although recommended, has not been attended with any better success than has followed the employment of the other remedies mentioned.

Joseph Collins.

ANISIC ACID, an isomer of methyl salicylic acid, is obtained by the oxidation of oil of anise. It crystallizes in brilliant, colorless crystals, slightly soluble in hot water, very soluble in alcohol and ether. It forms alkaline salts, which are freely soluble.

It possesses antiseptic and antipyretic properties resembling those of salicylic acid, but it is free from any of its disagreeable effects.

Locally applied as a powder to wounds or ulcerating surfaces it checks the secretion of pus and hastens repair.

Internally, the anisate of sodium is employed in all conditions in which salicylic acid is used. As an antirheumatic it is highly recommended. It is easily taken, and may be administered in doses similar to those of salicylate of sodium. *Beaumont Small.*

ANTHRAX, SYMPTOMATIC. The bacillus of symptomatic* anthrax was first obtained, in cultures which were known to be absolutely pure, by Kitasato. At first he was able to cultivate it only in a liquid medium made of the flesh of a susceptible animal †—*i.e.*, bouillon made from a guinea-pig. Subsequently ‡ he was able to cultivate the organism in ordinary neutral agar and gelatin. In order to obtain pure cultures he resorted to a special form of apparatus, also used in isolating the bacillus of tetanus (see under the heading Tetanus). The bacillus is an exquisite anaërobe. It will grow in deep stabs in tubes containing a large amount of agar or gelatin, to within a finger's breadth of the upper surface. The colonies in gelatin are irregularly spherical, with a warty surface. Subseqeuntly they have a ray-like zone of liquefaction and a dark centre. There is a production of gas, with a peculiar penetrating odor. Spores are formed at the temperature of the human body in thirty hours. These are oval, and have one side somewhat flattened, and form near to, but not quite in, the centre of the rods, which become spindle-shaped. Addition of grape-sugar, eikonogen, or other reducing agents to culture media, helps the growth of the organism. The bacilli have independent motion, but only when they do not contain spores. They do not lose virulence on solid media, but they do in guinea-pig bouillon.

Meade Bolton.

ANTOGAST. A thermal and climatic station in the Black Forest, Germany.

LOCATION.—Antogast is situated in a narrow valley of the Black Forest of Baden, about 1,500 feet above the level of the sea. Fine promenades in the surrounding pine woods make the place attractive. The springs are alkaline chalybeate ones, containing traces of arsenic. The waters are cold and pleasant to the taste.

ACCESS.—By omnibus from Oppenau, a station on the Oppenweier branch of the Baden Railroad.

INDICATIONS.—The waters are used both for baths and internally in cases of anæmia, neurasthenia, catarrhal affections of the organs of digestion and respiration. The *Kuranstalt* is equipped with modern appliances for the various hydrotherapeutic procedures. Season, June to October.

ACCOMMODATION.—There is a new *Trinkhalle* and some small hotels, and a number of lodging-houses. It is a quiet and cheap resort, but quite popular.

Edmund C. Wendt.

APOCODEINE is a reddish amorphous powder, almost insoluble in water, soluble in alcohol, ether, and chloroform. The hydrochlorate of apocodeine is a grayish amorphous powder, very soluble in water. It is obtained by heating hydrochlorate of codeine for fifteen minutes with a concentrated solution of chloride of zinc, at a temperature of 170° or 180° C. On cooling, a yellowish-brown mass separates from the liquid. This is drawn in thin, silk-like threads, and is almost pure hydrochlorate of apocodeine. The preparation is easy, and there is yielded a much greater product than the morphine salt; it is also much more stable. The base may be obtained by precipitating it from a solution by the addition of carbonate of sodium and extracting with ether.

The reaction of reagents upon apomorphine and apocodeine is almost identical, with the exception that the blood-red coloration produced by nitric acid is much more permanent with the latter.

This drug has recently been introduced as an expectorant and emetic. The dose is from $\frac{1}{10}$ to 1 grain. It is recommended in the treatment of chronic bronchitis, croup, whooping-cough, etc. A one or two per cent.

* Read symptomatic anthrax for sympathetic anthrax wherever this latter occurs in the article Schizomycetes. See this Handbook, vol. vi., p. 336, 2, eleventh line from the bottom.

† S. Kitasato: Zeitschrift für Hygiene, vol. vi., 1889, p. 105, Über den Rauschbrand-bacillus und sein Chlturverfahren.

‡ Ibid., vol. viii., 1890, p. 55.

solution may be prepared, and from five to ten minims administered. It acts rapidly, and the effect is prolonged. It may also be used hypodermically.

Beaumont Small.

ARISTOL is the registered trade name of dithymoldiiodide. It is prepared from thymol, $C_{10}H_{13}HO$, by substituting two molecules of iodoxyl, IO, for two of hydroxyl, HO. It contains forty-five per cent. of iodine. A moniodid and a triiodide have also been prepared. The latter has been called *annidalin*, and is used for the same purposes. Aristol may be made as follows: 1½ drachm each of thymol and caustic soda and 1½ drachm of potassium iodide are gently heated with enough distilled water to make 1 ounce 4½ drachms, and then cooled. This solution is added to eight ounces of a concentrated solution of hypochlorite of soda and agitated. The solution is then filtered and the precipitate washed with water and dried.

It is a light, reddish-brown powder, with a very faint odor, insoluble in water, slightly soluble in alcohol, soluble in ether, collodion, and oils. It should be carefully preserved, as it is decomposed by light and heat.

Therapeutically it is recommended for the same purposes as iodoform, but it is less active. Its advantages are that it is devoid of the disagreeable odor, and does not possess the toxic properties of the latter drug. It has been used in the treatment of eczema, psoriasis, scabies, chronic inflammation of the mucous membranes of the nose and pharynx, erosions of the os uteri, condylomata, granulating wounds, and ulcerating surfaces. It possesses the power of causing rapid cicatrization in a marked degree, and has proved of greatest service in the latter class of cases, particularly in the treatment of varicose ulcers. In lupus, tubercular and syphilitic ulcerations it was supposed to possess specific powers, but experience has not supported this view.

The powder is best applied by dusting on the part, or by insufflation; it may be used as an ointment, one part in ten, or dissolved in ether or collodion.

As it is partly eliminated through the lungs, it has been used in phthisis by hypodermic injections of a one per cent. solution in sterilized oil of sweet almonds. It is said to lessen the cough and night-sweats.

Beaumont Small.

ARSENICAL PARALYSIS.—Paralysis from arsenical poisoning has received little attention in treatises on nervous diseases. Most classical works on the subject do not even mention it. The most recent text-book on medicine, by Osler, gives it a short description. And yet this, though not the commonest symptom of arsenical poisoning, is not very rare. It was spoken of by Albani in the thirteenth century, and by others at an almost equally early period. Dana,[1] in giving the bibliography of this subject, cites more than one hundred articles published prior to 1887. Since Dana's publication I find about fifteen further articles, simply reports of cases, or more or less extensive dissertations on the subject. The absence of pathological data and the uncertain nosological position of the disease in part account for its apparent neglect. The last few years have partly removed these difficulties.

Etiology.—The largest number of cases of arsenical paralysis are due to acute poisoning, the poison being taken either by the mouth, designedly, or accidentally, or introduced into the system by external applications, as in the use of arsenical plaster. In all such cases the paralysis develops subsequently to the appearance of ordinary symptoms of acute arsenical poisoning. Paralysis from chronic arsenical poisoning is less frequent, but this statement must be accepted as applied to recognized arsenical paralysis, for doubtless many cases of chronic arsenical paralysis occur which are not recognized as such. The largest number of cases of paralysis from chronic poisoning are due to the internal administration of the drug. In some instances the quantity taken was quite small. Semple[2] reports the case of a boy of six, suffering with chorea, in whom, after the use of from three to ten drops of Fowler's solution three times a day for one month, there were brown pigmentation of the body, paralysis of the legs, chiefly of the toes and feet, with reaction of degeneration in the affected muscles and loss of the knee-jerks. Two months after the withdrawal of the drug the pigmentation had disappeared and the paralysis was better. A case of Hastings's,[3] who had taken three to five drops of Fowler's solution for some weeks, had burning pain in his feet and partial paralysis of the four extremities. A case of Hooper's[3] took five drops of Fowler's solution three times a day for six months. The drug was then discontinued on account of ophthalmia, but nevertheless the patient began to suffer with headaches and progressive paralysis, and died within a few months. Similar cases of paralysis following medicinal doses of arsenic have been reported by Jones,[3] Gaillard,[3] Dana,[1] and Ferguson.[4] These are the only cases in which I have found decided paralytic manifestations reported after the internal administration of medicinal doses, though less marked nervous disturbances are more common. It is noteworthy that in these instances such marked disturbances followed the administration of comparatively small quantities, whereas this remedy is so commonly used, often in large doses and for long periods, without toxic manifestations, and among the peasantry of Styria, who are accustomed to take arsenic regularly and continuously in quantities ordinarily toxic, no case of paralysis has been recorded. We are, therefore, justified in assuming that, in such instances, there is either some special predisposition to the symptoms manifested, or a special idiosyncrasy to the drug.* Other modes of chronic poisoning are from the external use of arsenic in salves, baths, etc., or contact with the poison as used in the arts and found in many fabrics employed in clothing, wall-paper, carpets, artificial flowers, etc. Barton[5] reports two cases, husband and wife, with almost typical histories of paralysis following acute poisoning — first the gastric symptoms, then pains and paralysis of the four extremities—where the man had for seven years been rubbing a mixture of four parts of arsenic to three parts of plaster-of-Paris into the skins of animals and birds, and the wife cleaned the room twice a week. Similar cases from dealing in stuffed birds, from working with arsenical draperies, or living in rooms where there were draperies or wall-paper containing arsenic, are recorded by Seeligmueller,[6] M'Clure,[7] Holm,[8] and Malmsten.[8]

Symptomatology.—The symptoms vary to some extent, according to the amount of arsenic taken and the manner of poisoning, that is, whether it were acute or chronic. But where well-marked paralyses have developed there is usually considerable uniformity in the clinical pictures presented. In cases of acute poisoning the paralytic manifestations appear shortly after the disappearance of the severe gastro-intestinal disturbance. Paralysis of twenty-four hours' duration immediately after the ingestion of the arsenic has been spoken of, but must be rare or escape detection. The onset of the paralysis occurs usually from several days to several weeks after the poison has been taken. It is commonly preceded by sensory symptoms, tingling, numbness, intense pains, etc. The paralysis itself begins more or less gradually. Not uncommonly its onset is not observed, but when the acute symptoms have subsided and the patient attempts to get out of bed it is found that he cannot walk or cannot hold anything in his hands. Occasionally the paralysis is complete, or at least no longer progressive, at an early period, but usually some weeks elapse before it has reached its greatest intensity. Almost always, when observed from the beginning, it has been found to commence at the distal ends of the extremities, the fingers and toes—usually first in the lower extremities,—and

* Jaccoud (Brissaud, Des Paralysies toxiques, 1887) says alcoholic excesses constitute one of the most active predisposing causes of arsenic poisoning, but in the study of the literature I have found no cases to substantiate this view. According to Putnam, while arsenic is usually eliminated in from twelve to twenty days, there are cases in which it is found months after it had been taken. Possibly it is this slow elimination that favors chronic poisoning from ordinary medicinal doses.

thence extends upward. The parts below the knees and elbows are most profoundly paralyzed. Some writers state that the paralysis does not extend above the knees and elbows, but, possibly, in all cases where the paralysis has been profound, other muscles, especially of the thighs, have been at least paretic. I shall report a case below where the legs were completely paralyzed and even the muscles of the trunk were affected. The extensor muscles—the radial group in the upper, and anterior tibial group in the lower, extremities—are as a rule most profoundly affected. When the paralysis is complete the paralyzed muscles are quite flaccid, and we find wrist-drop, foot-drop, etc. At a later period there are very frequently contractures, more or less strong, affecting particularly the least paralyzed muscles. Tremor, often fibrillary in character, is not infrequently observed in the affected muscles. The paralysis just described, affecting the four extremities, the lower more than the upper, is that usually found. In rare instances it is otherwise distributed; sometimes in hemiplegic, and more rarely in monoplegic form. In almost all instances there is a great loss of flesh, a general wasting, but in addition there is special and pronounced atrophy of the paralyzed muscles. The electrical reactions are those of peripheral paralysis. The reaction of degeneration—no muscular contraction when either current is applied to the nerves, or when the faradic current is applied to the muscles, contraction of the muscles, but a reversal of the normal formula, when the galvanic current is applied to them, that is, the anode closure contraction occurs more readily than the kathode closure contraction, and the resulting contractions are tardy, sluggish, not the quick, lightning-like contractions of normal muscles—becomes more or less pronounced a few days, or a few weeks, after the occurrence of the paralysis. At a later period, if the paralysis be profound, all electrical reactions may cease. In some instances slight changes in electrical reactions may be observed before there is any manifest paralysis, particularly that it requires a stronger faradic current than usual to produce muscular contractions. In lighter cases such electrical responses, especially in the anterior tibial group of muscles, may be the only indication of incipient paralysis.

The sensory symptoms are at times even more pronounced than the motor paralysis. These symptoms are paræsthesiæ of various kinds, tingling, numbness, "deadness," coldness, etc.; pains, tenderness, and anæsthesiæ. As a rule the tingling and numbness, and very frequently the pains, precede the paralysis. The pains are often intense and the most distressing element in the disease. They are usually described as burning, cutting, boring, etc., and are often accompanied by sudden starts, cramps, or spasmodic movements of many muscles of the body. They are usually more or less paroxysmal, and are likely to be worse at night and keep the patient awake. They occur most frequently in the feet and hands, sometimes appear to be in the joints or bones, and occasionally in the course of the nerves. Tenderness of the affected muscles is also a common and prominent symptom. The tenderness may be so great as to make the handling of the patient extremely painful, and, on account of the suffering produced, electrical examinations become very difficult. In some instances the tenderness is observed to be in the course of the nerves, but generally it is so diffused that it is hard to state that it is especially over the nerve-tracts. Often hyperæsthesia or hyperalgesia is observed, although this may be only an expression of the great tenderness. Loss of, or impaired sensation, anæsthesia, is also a common symptom. It is found most frequently in the feet and hands, and especially the finger-tips and toes or soles of the feet, although it corresponds somewhat to the extent of the motor paralysis. It has been found to follow the distribution of certain nerves. For instance, in a case of Seligmueller's it was limited in the upper extremities to the distribution of the median nerves. Probably in all cases where there is extensive paralysis, anæsthesia occurs, but it is likely to disappear much sooner than the paralysis, so that it may be reported as absent, when the patient is seen some time subsequent to the inception of the nervous symptoms. Sometimes there is only loss of cutaneous sensation—sensation of touch is impaired and the patient cannot feel things with his fingers, does not know that he is holding something in his hands, etc. With the loss of tactile sensation there is likely to be loss of the sensation of temperature and pain. Sometimes loss of muscular sense is very marked, the patient does not know the position of his limbs, etc. In all cases of marked paralysis, the patellar tendon reflex, if spoken of at all, was reported to be absent. It was also found to be absent, or lessened, when the paralytic manifestations were not very pronounced. When once lost, the knee-jerk is slow to return. Various vasomotor and trophic changes are common, as slight œdema, particularly of the feet, profuse perspiration, loss of the nails and hair, and desquamation of the epidermis. Not rarely there is a brownish pigmentation of the skin; even herpes zoster has been observed. Muscular atrophy has already been mentioned. The clinical picture would not be complete without the statement of some symptoms that are as invariably absent. That is, the cranial nerves are never affected, there is no decubitus, and the functions of the bladder are always found to be intact.*

As has already been stated, usually several days or several weeks elapse before the disease reaches its acme. Then, after an interval, which may be of only a few days' duration, but sometimes runs into months, the patient begins to improve. The anæsthesia almost always begins to disappear before the motor paralysis. It disappears in the reverse order of its appearance; first from the trunk and the upper part of the extremities, remaining longest in the fingers and toes. The motor paralysis disappears in the same manner—first in the upper part of the extremities, then in the muscles below the knees and elbows. The flexors usually improve more rapidly than the extensors, leaving the only motor symptoms manifested in slight cases, paralysis of the extensors of the feet and toes, and of the extensors and small muscles of the hand. At a late period there are liable to be contractures in the still paralyzed parts. The pains also become modified in intensity after the lapse of some time, but unfortunately they are likely to persist with a greater or less degree of severity throughout the whole course of the disease. The vaso-motor symptoms, œdema, pigmentation of the skin, etc., usually disappear at a comparatively early period. The whole duration of the disease is extremely variable. Alexander puts it as from eight days to a number of years. It may be stated in general that mild cases usually get well within six months, possibly in a few months, whereas in severe cases one or two years elapse before there is complete recovery, or, in those cases in which a cure remains incomplete, before there is a definite cessation of improvement.

Dana has described a form of arsenical paralysis as pseudo-tabes, in which ataxic manifestations are prominent. In a few cases the symptoms of motor incoördination are more prominent than those of paralysis, so that to these, as there are also sensory symptoms, the term pseudo-tabes seems quite appropriate. But ataxia is spoken of in many cases after the motor paralysis is beginning to disappear, when it is really the remains of the paralysis. In fact, a degree of paralysis has been, or is, present in all these cases of pseudo-tabes, distinguishing it in this respect from true tabes, but it may be in so far deserving of a special name as the motor incoördination may, in part at least, be due to sensory disturbances, impaired muscular sense, etc., which doubtless in part explain true ataxia.

The disease, as so far described, is that following acute arsenical poisoning. In some cases following chronic poisoning the symptoms are much the same, only the

* Optic neuritis is spoken of in two cases, that of Dana (Brain, January, 1887) and of DaCosta (Medical Times, 1881, p. 385). Putzel (Medical Record, June 2, 1888) merely mentions, without further detail, that he had seen a case of acute arsenical paralysis in which there was paralysis of the bladder and rectum.

onset is likely to be less sudden and the symptoms less profound. In other chronic cases the symptoms are very slow in appearing, and may have been in part masked by the symptoms of gastric irritation. The pains are likely to be proportionately greater, and the paralysis slight in degree. But, even when the paralysis is slight, the changes in the electrical reactions are likely to be found. In such instances the motor manifestations may be rather like those of ataxia than of paralysis. Sometimes a sense of profound prostration is the only indication of motor impairment.

There is another class of cases in which the poisoning appears to have been exceedingly slow and insidious, the symptoms usually very obscure, the cause arsenical wall-papers or the like. Among the symptoms in these instances are, gastro-intestinal irritation, neuralgia, headache, insomnia, general prostration, mental depression, impairment of memory and mental endurance, and epileptiform convulsions. As this article is devoted to arsenical paralysis no further attention will be here given to this class.

In order to illustrate the picture of arsenical paralysis, and inasmuch as such cases are comparatively rare, I shall give the history of two cases which have come under my own observation. The report of the first, of which I have few notes, will be necessarily fragmentary.

A drayman, seventeen years of age, on September 8, 1886, ate by mistake a piece of bread on which "Rough on Rats" had been spread. For four days he had acute gastro-intestinal symptoms, vomiting, prostration, etc. A few days afterward he was again driving his team, though he was feeling very weak. Between two and three weeks after the arsenic had been taken he observed that his legs were getting weak, and some time later the same condition was observed in the arms, though he worked for a week after these symptoms began to appear. Six weeks after the poisoning he was unable to walk alone; there was paralysis of muscles of the leg, especially of the dorsal extensors of the feet and toes, paralysis of the extensors of the fingers, and impaired cutaneous sensation in the same parts. He suffered with severe pains in the arms and legs, and there was excessive tenderness over the paralyzed muscles. He also complained of a sense of numbness and tingling in his extremities. His hands felt numb; he could not tell by the sense of touch that he had anything in his hands. Patellar tendon reflex absent on both sides. The paralyzed muscles did not respond to the faradic current. About a month later he had improved so much that he was able to walk without assistance. His own statement is that he began working nine months after he had been poisoned, but he thinks it was fully a year, or a year and a half, before he had regained his full strength. At present he is again acting as drayman, does heavy work, lifts heavy loads, showing a full restoration from the disease. Its only traces are that he becomes fatigued more easily than before the accident, and is somewhat constipated, which had not been his former habit.

The second case, a man, thirty-five years of age, contractor, on account of financial losses, took Paris green with suicidal intent. He suffered for several weeks with violent gastro-intestinal disturbance, and six days after the poisoning he became violently maniacal, and remained so for several days. It was observed when he got out of bed, several weeks after he had taken the poison, that he was weak on his legs, and that his hands trembled. One week before I saw him, which was seven weeks after the poisoning, he became bedridden on account of his inability to walk. He began suffering with severe pains in his arms and legs, even before the paralysis was observed. When I saw him, June 6, 1892, there was absolute paralysis of the feet and ankles, muscles flaccid, foot-drop, considerable weakness of the extensors and flexors of the knee, and some weakness, though less, in the hips. The upper extremities were quite paretic; fingers and hands almost paralyzed, pronation and supination very feeble, the flexors and extensors of the elbows also much weaker than normally, and the muscles of the shoulder slightly paretic.

There was more or less anæsthesia in the paralyzed parts, most profound in the legs. Over the latter firm pressure could not be felt, as far as the gluteal region. A pin-prick was recognized but was not painful. In the upper extremities anæsthesia was most pronounced in the hands and back of the forearms. There was considerable tremor of the fingers on attempted movement. Patellar tendon-reflex absent on both sides. All the muscles respond to the faradic current, but the left peroneal group requires a stronger current than normally. There was considerable tenderness over the left calf and over both crural nerves. He suffered intensely with pains, either burning or boring in character, sometimes feeling as though the limbs were in a vise, the pains being often attended with starts and spasmodic movements. The pains were worse at night and kept him awake. The muscles of the trunk seemed normal, and sensation was normal in the same part. No symptoms on the part of the cranial nerves, bladder, or rectum. The optic disks were normal.

June 17, 1892.—No power in the legs whatever. Paresis of the muscles of the trunk and slight anæsthesia. Upper extremities weaker than at last note. Some œdema of the right fingers. The pains appear to be worse and are often attended by spasms, opisthotonic in character. A great tenderness over all the paralyzed muscles and joints, movements of the joints excruciatingly painful. This tenderness makes the electrical examination very painful and difficult. Only the left peroneal group of muscles was examined. They do not respond to the faradic current; the anode closure contraction obtained before the kathode closure contraction.

June 28th.—Sensation decidedly better, pains and motor paralysis unchanged.

July 12th.—Sensation much improved. He has some power in the knees and hips, there is increased strength in the upper extremities, and the pains are less severe.

On the date of this writing, November 26th, a little over seven months after the date of the poisoning, cutaneous sensibility is normal, or nearly so, everywhere. The left arm and hand have almost regained their normal strength. In the right upper extremity the fingers, especially the extensors, are quite weak; muscles of the elbow have a fair amount of strength, though weaker than normal; those of the shoulder are more paretic than those of the elbow. In the lower extremities there is some power in the muscles of the hips and knees, but very slight, while the ankles and feet are still completely paralyzed, and the feet are held rather firmly in the position of talipes equinus. There is still a little tenderness about the right upper extremity, especially over the muscles of the hand, far more over the muscles of the legs, though the latter does not compare in intensity with what it was some months ago. The pains are also far less severe and less frequent. They are still worse at night, and often keep him awake.

Pathology.—Leyden in his classical work on "Diseases of the Spinal Cord," published in 1875, spoke of neuritis as the cause of arsenical paralysis. Subsequently a number of writers (DaCosta, Mills, Seguin) attributed it to myelitis. Of late years there has been a certain unanimity of opinion that neuritis is the real pathology, an opinion with some experimental and post-mortem observations to substantiate it; but quite recently in one case decided changes were found in the central nervous system, and it is yet to be seen to what extent the views on the subject will thereby be revolutionized.

The experimental investigations in this direction are not all in accord. Popow, experimenting upon dogs, produced acute or chronic poisoning by means of larger or smaller doses of arsenic, and found thereafter myelitis, especially of the anterior cornua. Kreyssig and Schulze, repeating Popow's experiment, did not find any pathological changes in the cord. Some control experiments, showing how easily methods of hardening and staining may give the appearance of morbid changes in nerve-tissues, lead them to infer that Popow's description was, chiefly, of such artificial products. More recently, Alexander experimented on rabbits. After pro-

ducing paralysis of the posterior extremities by means of arsenical poisoning, he found the cord to be normal, while there was extensive neuritis and primary disease of the muscles. He attributed the inflammation in muscles and nerves to the occlusion of innumerable capillaries, which he supposed were primarily attacked by the poison.

Two post-mortem examinations in man have been reported.* The first was a case of Ferguson's.[4] The patient, a consumptive, took for a lengthy period Fowler's solution, twenty to thirty drops three times a day, which had been recommended as a cure for consumption, and was not discontinued when diarrhœa and headache came on. When seen by Ferguson the face was brown and mottled, there was impairment of cutaneous and muscular sensation, tenderness and intense pain in the legs, extending to other parts of the body; the gait was paretic, the most marked paralysis being in the anterior tibial group of muscles, in which the reaction of degeneration could be obtained. She died shortly afterward of phthisis. At the post-mortem examination evidence of neuritis was found in many of the peripheral nerves—the nerve-sheaths and connective tissue swollen and infiltrated, the medullary sheaths and axis-cylinders broken up—as well as marked degeneration of the muscles. In the very brief report there is also a simple statement of disorganized cells being found in the cord. The second case, the one above referred to as possibly having a revolutionizing effect on the present views of the pathology of this condition, is one of Erlicke and Rybalkin's,[9] a man of fifty, who died twenty-six months after the arsenical poisoning. Shortly after the poisoning there was paralysis of the four extremities, and at the time of his death—due to a subsequent chronic lung disease—there were still paralysis and contractures in the hands and feet, attendant muscular atrophy, pains in the feet, and absent knee-jerks. The post-mortem revealed distinct changes in the anterior cornua throughout the cord—the morbid appearances not extending above the pyramidal crossing—especially in the cervical and lumbar enlargements, affecting both the nerve-cells and the fine net-work of fibres. There was a great reduction in the number of cells, both in the anterior cornua and in the area between the anterior and posterior cornua. The cells remaining were not normal, their protoplasm was altered, and they were either rounded in outline, reduced in size, had fewer processes, or were without nuclei. Some cells had vacuoles in them, others contained leucocytes. The nerve net-work in the anterior cornuæ was mostly replaced by fine neuroglia. Of the nerves, only the radial and perineal were examined, and presented distinct evidence of neuritis. The nerves were found to contain normal and degenerated fibres, as well as regenerated ones. The authors conclude that there was a chronic pathological process in both cord and nerves, and that it began about the same time in each. They suppose that the cause was, not the entrance of the poison into the cells, but the changes produced by the arsenic in the circulation and the blood.

The clinical manifestations of arsenical paralysis, and it is chiefly upon these that the views of its pathology have hitherto been based,† point strongly to neuritis as the basis of the paralysis. The paralysis, evidently of a peripheral character, with rapid development of atrophy, and the reaction of degeneration, as well as the sensory symptoms, are very easily explained by neuritis. It is true that a poliomyelitis produces the same kind of paralysis, but the sensory disturbances cannot be explained by poliomyelitis and scarcely by a more diffuse myelitis. The full restoration to health, as occurs in most instances, is altogether at variance with such an explanation, and the invariable absence of paralysis of the bladder and decubitus, symptoms so common in extensive myelitis, is strong evidence that myelitis does not account for the symptoms. Furthermore, the occasional impairment of a single nerve, as anæsthesia limited to the area supplied by the median nerve, and the presence of herpes zoster, are proofs that neuritis must be present in such instances. In the foregoing is sufficient proof that there must be neuritis in these cases, but it does not follow that we have only neuritis. The post-mortem mentioned, as well as some clinical data, indicates that there are, sometimes, at least, also changes in the cord, myelitis. The clinical manifestations force the belief that neuritis is the chief and most extensive pathological condition, and largely the cause of the symptoms, but, it is not improbable that in those cases where there is permanent paralysis there has been more extensive myelitis, which in itself has produced many, if not most, of the symptoms. In the case of Erlicke and Rybalkin, with such extensive changes in the cord, the permanent paralysis was greater than in any other case I have seen reported. In some cases of chronic neuritis it is probable that the latter is due to changes in the trophic centres of the cord, and, possibly, a similar relationship exists in many cases of multiple neuritis. As arsenical paralysis sets in, as a rule, a few weeks after the poisoning, and both the post-mortem examination of Popow above given, and the frequent occurrence of delirium soon after the poisoning, indicate that the central nervous system may be affected at a much earlier period, the thought occurs that the extensive neuritis in these cases may be really due to prior and slighter changes in the cord. With this view, morbid changes in the cord would be the rule, but they would, usually, be slight and their effects transitory. But it is more probable that so far as the two conditions, neuritis and myelitis, occur together, they are independent of one another, and each due to the circulatory and blood disturbances produced by the arsenic.

We may then summarize the foregoing by saying that neuritis is the chief pathological condition producing arsenical paralysis, that where there is permanent paralysis there is more or less extensive myelitis, while in curable cases, if myelitis be at all present, it must be of a mild grade.

Diagnosis.—When it is known that the patient was poisoned with arsenic, as is usual in acute cases, the cause of the resulting paralysis is apparent. When there is no such knowledge the history of severe acute gastro-intestinal disturbance preceding the kind of paralysis just depicted should be almost enough to make the diagnosis certain. The picture of the paralysis is almost characteristic: the four extremities usually affected—the lower more frequently and more extensively,—the paralysis being always greatest in the digital extremities and attended by atrophy and altered electrical reactions, the absent knee-jerks, the intense pain and extreme tenderness, and the absence of bladder symptoms and decubitus.

When the paralysis is less marked, and the whole array of symptoms less conclusive, the greater prominence of the sensory symptoms and the presence of altered electrical reactions in the slightly paralyzed muscles—in this instance it requires a very careful examination to reveal such reactions—may arouse a suspicion of the true condition.

The cases with ataxic gait may resemble locomotor ataxia, and Seeligmueller mentions a case of his own which was falsely looked upon as one of locomotor ataxia. The severe pains and lost knee-jerks heighten the resemblances of the two diseases. But with careful examination such errors will rarely occur, for it will usually be found that the difficult gait is rather paretic than ataxic, and, furthermore, symptoms on the part of the bladder and the eyes, such common and early manifestations in locomotor ataxia, are absent.

* A case of Popow's (Virchow's Archiv, cxii., 2) should be mentioned, though not strictly belonging here, as the man died thirty-two hours after the poisoning. The vessels of the cord were distended, there were numerous smaller or larger hemorrhages into the cord, and, in some parts, plastic exudation, the changes being chiefly in the cervical and dorsal regions, especially their central parts. Some cells were clouded, their nuclei indistinguishable, and were nearly or altogether without processes.

† The similarity of the clinical picture to that of alcoholic neuritis has also furnished a strong ground for pronouncing this neuritis. But it has recently been denied that all the lesions in alcoholic paralysis are peripheral ones.

In cases of chronic poisoning the detection of arsenic in the urine may assist materially in diagnosis. In acute cases the arsenic has usually been eliminated before or soon after the paralysis appeared.

PROGNOSIS.—Mild cases may get well in a few months, though rarely less than six, but when there has been profound paralysis recovery cannot be expected in less than one or two years.

The prognosis is always favorable in so far that most cases recover, and all, if they survive, improve very much, but there is prevalent a too favorable opinion of the curability of the disease. For instance, Dana says almost all cases recover. I have carefully examined all the reports of cases made in recent years; twenty-two in number. Of these, two died, two recovered, and the other eighteen were still uncured at the time of the reports, from two months to several years after the inception of the paralysis. It may be assumed that of those reported at an early period most, or all, recovered. But a number were reported after more than a year had elapsed, and in four cases—those of Putzel,[11] Peterson,[10] Erlicke and Rybalkin[9]—after a lapse of two years or more, paralysis, more or less extensive, remained, indicating permanent impairment.

If we can draw any conclusions from such small numbers we may say that in twenty per cent. of the cases, or more, there will not be full restoration to health. I have already ventured the opinion that in the latter cases myelitis is present.

TREATMENT.—The first object must be to eliminate the arsenic from the system as rapidly as possible, for which purpose iodide of potassium seems to promise most, and has been almost universally used in such cases. Only moderate doses are indicated. Leyden suggests warm and sulphur baths. For the pains, often excruciating, opium or morphia is demanded.

Further than this the indications are, the toning of the general system—for poor nutrition and great prostration are rarely missing—by careful feeding, strychnia, iron, and the direct treatment of the paralysis by electricity, massage, counter-irritation, etc. It can scarcely be doubted that in the most cases the tendency is to recovery, and the patient gets well quite irrespective of treatment.

ARTHRITIS DEFORMANS. In the differential diagnosis it is important to keep in mind that this disease, beginning its destructive work with the articular cartilage, and progressing without suppuration, will lead to gradual but very considerable diminution of the articulating surfaces, and to osseous proliferation with excrescences at the periphery of the joint. The form and shape of the affected joint, particularly of the caput femoris, will consequently be considerably altered, flattened sometimes like a mushroom, but the mobility is generally not abolished, and anchylosis, as we see it in certain cases of chronic rheumatism, does not occur. While at the commencement of the disease it will often be difficult to distinguish the same from chronic rheumatism, a correct diagnosis will be obtainable later on. Arthritis urica, real gout, which produces alterations of the small joints of the hands and feet, similar to those made by arthritis deformans, has its periodical, often intensely painful, paroxysms, quite different from the mild exacerbations of arthritis deformans.

Aside from the great value of prolonged and often repeated plain warm baths at home, or in thermal watering places, in the general management of the disorder, steam-baths, steam-douches, sulphur- and mud-baths may also be used. In overcoming or correcting and improving contractures and false positions, and relative immobility of the joints, it is well to employ massage and mechanico-therapeutics, the action of which may again be supported and maintained by orthopedic apparatus. Intercurrent exacerbations are to be treated by mild antiphlogistics and counter-irritants. In extreme cases of deformity the question of surgical interference, *i.e.*, resection of joint, might come up, but there is not as yet sufficient experience to serve as a guide in that direction.

Leonard Weber.

ARTIFICIAL FEEDING OF INFANTS. During the past few years the subject of the artificial feeding of infants has still claimed much attention from the profession, both in Europe and in this country, and several distinct advances may be noted. The various lines of investigation mentioned in my previous article, Vol. VIII., had made us aware of many of the difficulties which lay in the way of obtaining a perfect substitute for mother's milk. Cow's milk, or some preparation of it, was universally regarded as the only efficient basis for a good working substitute, and it was hoped that the difficulties, which had previously been encountered in its administration, could now be overcome. At the date of the previous paper the situation might be briefly stated as follows:

1. Our more definite knowledge of the chemical composition of the two milks enabled us to alter the substitute so as to render it the chemical analogue of mother's milk.

2. By means of the process of sterilization at the temperature of 212° F., we were able to secure a practically sterile food, and thus to avoid the introduction of myriads of bacteria, with all their poisonous possibilities, into the infant's stomach.

3. Our more exact knowledge of the capacity of the infant's stomach enabled us to regulate the proper amount of food to be given at a time, and thus to guard against the evils of over-feeding.

Thus, theoretically, we appeared to be able to supply the infant with an ideal food, a close approximation in chemical composition to mother's milk, absolutely sterile, in proper amounts, and at sufficient intervals to insure due digestion and nutrition. In practice these measures, carefully carried out, yielded gratifying results in some cases, but in many others hopes were disappointed. Among those reporting results we may mention Dr. Koplik,[1] of New York, who, with a large experience among dispensary patients, found milk thus prepared and sterilized of distinct benefit in acute cases, but was disappointed with the results obtained in chronic cases of gastro-intestinal disease. Dr. Davis,[2] of Philadelphia, found nutrition under its use distinctly fail. Corroborating this clinical experience were the results obtained by Dr. Leeds[3] from investigations in the laboratory on the changes produced in milk by the prolonged heat necessitated by this absolute sterilization. His results were stated as follows:

1. The starch-liquefying ferment, galactozymase, which exists in normal cow's milk in minute quantities, is destroyed when the heat rises much above 165° F. (75° C.).

2. A portion of the lactalbumin is coagulated, thickening the milk and intensifying its colloidal properties.

3. The casein, after the action of the prolonged heat, is less readily coagulated by rennet, and yields only slowly and imperfectly to the action of pepsin and pancreatin.

4. The fat-globules are injuriously affected by this heat. The fat, to some extent, is freed, and, after standing, small lumps of butter-fat are sometimes observed on the surface of the milk; while the portion not freed has a decidedly lessened tendency to coalesce. This is possibly owing to the coagulated proteid matters attaching themselves to the minute fat-globules, thus preventing their coalescence. It was also found that when sterilized and unsterilized portions of milk were churned, and a note made of the time required to form appreciable

amounts of butter, the unsterilized yielded a larger amount in considerably less time than the sterilized.

5. Milk-sugar by long-continued heating is completely destroyed; that it undergoes some change during the process of sterilization, is shown by a lessened dextro-rotatory power.

It would appear, therefore, that milk sterilized for any prolonged period at a temperature of 212° F. must be regarded as distinctly less readily and less perfectly digestible than raw milk. The destruction of the galactozymase, the coagulation of the lactalbumin, and the alteration of the casein, so that it becomes more slowly acted on by rennet, all presumably diminish its digestibility by the gastric juice of the infant; while the changes in the fat-globules can be shown to interfere to a large extent with their digestion and assimilation.

The question arose, therefore, whether it was not possible to avoid the disadvantages of this prolonged and absolute sterilization, and yet obtain a practically sterile food, the importance of having such being recognized on all sides. This was answered in the affirmative by Dr. Leeds. He found that milk rendered feebly alkaline, and heated, as soon as received in the morning, to a temperature of about 155° F. (somewhat short of the degree of heat necessary to coagulate the galactozymase) is rendered practically sterile. "It is evident," he says, "in the first place, that no milk having an acid reaction is in a proper condition to be heated, because of the effect of acidity upon coagulation, and inasmuch as cow's milk, as delivered to consumers, has usually developed a notable acidity, the addition of the requisite amount of a suitable alkali is the first point to be considered."

By experiments he found that to neutralize this acidity it required about 2½ grains sodium carbonate, or 9 drachms ordinary lime-water, to the pint of milk. Even this appeared to limit the development of some of the bacteria. Dr. Leeds says: "On making gelatine-peptone cultures, one drop of the original milk yielded 400 colonies of bacteria after five days' culture at common temperatures, while the same milk rendered feebly alkaline with lime-water yielded only 230 colonies. In some other experiments that he quotes the result was even more striking. After the milk was thus rendered slightly alkaline he tried the effects of lower temperatures. It was found that such milk maintained at a temperature of 155° F. (68° C.) for an hour proved practically sterile. Shorter periods were then tried, and an equally good result was obtained at the end of twenty minutes (only one to two colonies per drop). On cooling and diffusing the cream, which the heating had brought to the surface, the appearance and properties of the milk thus heated and prepared in nowise differed noticeably from raw milk.

A difficulty arises in securing the proper amount of heat, if we are to have this degree of sterilization carried on in the household. At my suggestion, a series of experiments were made with milk contained in glass flasks and heated in an Arnold sterilizer. It was found that with the water in the sterilizer and the milk in the flasks at ordinary temperatures, on placing the sterilizer over an ordinary Bunsen gas-burner it took about twelve minutes for the milk in the flask to reach the temperature of 155° F. If now the gas be turned out, and the milk be left in the sterilizer for another ten minutes and then removed to a cool place, all the sterilization necessary will have been effected and none of the deleterious changes will have taken place.

More lately, however, Dr. Freeman,[4] of New York, has devised a very simple apparatus, by which the milk to be sterilized is immersed in water at the boiling-point, the amounts being so proportioned that as the temperature of the water is lowered the milk is raised to the necessary heat of 165° F. The apparatus consists of two parts, a pail for the water and a tray containing a set of zinc cylinders which are to hold the bottles of milk. The pail is a simple tin pail with a cover. On its side is a groove indicating the level up to which it is to be filled with water. The tray is made in two sizes; one which will hold ten six-ounce bottles, the other seven eight-ounce bottles. The first is suitable for infants below six months of age, the second for those older. The pail is filled with water up to the groove, and placed on the stove to boil. The bottles are filled with milk and stoppered with a pledget of cotton, and then dropped into their places in the cylinders. Sufficient water is now poured into each cylinder to surround the body of the bottle. This is necessary for the conduction of the heat. When the water in the pail boils briskly, it is taken off the stove, and placed on a mat or table; the lid is removed, the tray containing the bottles of milk is placed inside and the lid replaced. The whole is allowed to stand half an hour, after which the bottles of milk are to be taken out and cooled rapidly, either by placing them on ice in a refrigerator, or by standing them in cold or ice water, which should be changed occasionally as it becomes heated. Milk thus prepared shows no change for several days.

Mr. Dyer, a pharmaceutical chemist in this city, has made a sterilizer for me, according to these instructions, and, after careful experimentation to obtain the correct size, has furnished me with the following dimensions: The tin pail should be 8¾ inches deep, 10½ inches in diameter, 5¼ inches to water-line. The zinc cylinders should be 6½ inches deep, 2⅝ inches in diameter. There are seven cylinders in the tray; the bottles of milk hold eight ounces each. With the milk and the water in the zinc cylinders at a temperature of 65° F., the following is the memorandum of the temperatures obtained in this apparatus:

In ten minutes the milk in the bottle reached the average temperature of 164° F.; in twenty minutes, 166° F.; in thirty minutes, 164° F.; in forty minutes, 161° F.; in fifty minutes, 158° F.; in sixty minutes, 154° F.

Dr. Freeman in his paper says, "I have made a series of experiments at the Bacteriological Laboratory of the College of Physicians and Surgeons, to test the efficiency of this apparatus in the pasteurization of milk. Specimens of milk obtained from different sources and at different times have been examined to determine the number of bacteria contained in one cubic centimetre before and after pasteurization. And while the raw milk used contained from 8,000 to 230,000 to each cubic centimetre, the same milk after this pasteurization practically contained none." This process he finds quite sufficient to destroy most of the ordinary bacilli found in milk, and tubercle bacilli. He quotes Van Gruns as stating that it also kills the typhoid bacillus, the cholera bacillus, and the pneumococcus of Friedländer. It does not appear in any way to affect the milk.

Dr. Rotch,[5] of Boston, has reduced the artificial feeding of infants to a still more exact system. As the result of much clinical experience he concludes that slight changes in the percentages of the three elements of milk of which we have the most accurate knowledge, namely, the fat, sugar, and albuminoids, are of real practical value in managing the digestion and nutrition of the infant.

Infants, like adults, require special modification in their food to suit the particular digestion of the individual. To prove this he presented the analyses of several human milks. In these analyses the fat, sugar, and albuminoids varied to a marked degree, and yet the infants all digested and throve well on their special percentage, while what agreed with one produced at times serious symptoms in another. He considered, therefore, that, so far as milk is counted upon as a food, it should be understood as a general name for a composite meal, the special ingredients of which should be modified to suit the digestion of the individual infant. To obtain this possibility Dr. Rotch established a milk laboratory where physicians could send prescriptions for milk of a definite formula, and have them dispensed accurately. The milk used in this laboratory is obtained from a herd of cows, of special breed, and so systematically fed that the analysis of their milk is of almost unvarying percentage. The morning milk of these cows, milked into glass, and kept scrupulously clean, is rapidly cooled, and is delivered at an early hour at the laboratory. Here, by means of a separator, a stable sixteen per cent. cream is

separated from the milk. The amount of albuminoids in the separated milk is known, and by means of a sugar-of-milk solution of definite strength, the amount of the sugar is carefully adjusted. As the chemistry of the mineral matter in woman's milk is little known, for the present that element is ignored. In writing a prescription, therefore, the three average percentages, namely, those of the fat, sugar, and albuminoids—4, 7, and 1.50—have only to be remembered, and starting with these figures any of the ingredients can be increased or decreased according to the need of the special infant.

In dispensing the prescription, the superintendent of the laboratory from the above materials is able, by a comparatively simple calculation, to dispense a milk containing the exact proportions ordered. The quantity required for each feeding is placed in bottles corresponding in number to the number of times that the infant is to be fed in the twenty-four hours. The day's food, each feeding in its own bottle, is then placed in a basket, or suitable receptacle, and sterilized for half an hour at a temperature of 167° F. It is then ready to be sent out to the infant. When the time for feeding arrives, the nurse takes a bottle from the basket, warms it, replaces the stopper by a suitable nipple, and gives it to the infant.

The following are given by Dr. Rotch as examples of suitable prescriptions for infants at varying ages, and under varying conditions:

1. For a healthy baby, four months old and normal weight, milk to be of following composition:

Fat	4.0
Milk-sugar	7.0
Albuminoids	1.0

Send six tubes, each four ounces, with lime-water one-twentieth. To be sterilized at 167° F., for twenty minutes. Feed every three hours.

2. For the same baby sick, albuminoid digestion weak, as evinced by vomiting, colic, and curds seen in the dejections, milk of following composition:

Fat	3.0
Milk-sugar	6.0
Albuminoids	0.50

Send eight tubes, each containing three ounces, with lime-water one-tenth. Sterilize as above. Feed every three hours.

3. For an infant six months old in whom the sugar digestion is weak, milk of following composition:

Fat	3.0
Milk-sugar	4.0
Albuminoids	2.0

Send six tubes, each containing six ounces, with lime-water one-twentieth. Sterilize as before. Feed every three hours and a half.

4. For an infant twelve months old with duodenal jaundice, milk of following composition:

Fat	0.50
Milk-sugar	5.00
Albuminoids	4.00

Send five tubes, each containing eight ounces, with lime-water one-eighth. Sterilize as above. Feed every four hours.

The exact capacity of the infant stomach, as regulating the quantity of food to be allowed at each time of feeding, is a matter of much importance. At the meeting of the American Pediatric Society in 1890, Dr. L. Emmett Holt[6] read a paper on this subject, in which he gave the result of his observations at one hundred and forty-two autopsies. Very careful precautions were taken to insure as accurate data as possible. The measurements obtained in ninety-one cases he tabulates as follows; the others, most of them his earlier cases, being discarded on account of imperfections in the methods employed:—

Table showing Average Capacity of the Stomach in Ninety-one Cases.

Age.	Number of cases.	Average capacity.	
		Ounces.	
Birth	5	1.2	
Half month	7	1.5	
One month	4	2.0	
One and a half month	11	2.27	
Two months	4	3.37	
Two and a half months	2	4.25	
Three months	6	4.50	
Three and a half months	3	5.00	
Four months	4	5.62	= 5 average.
Four and a half months	5	4.50	
Five months	4	5.62	
Five and a half months	2	5.25	= 5.75 average.
Six months	8	5.94	
Seven months	6	7.00	
Eight months	3	6.66	= 6.88 average.
Nine months	—	—	
Ten months	5	8.40	
Eleven months	2	7.50	= 8.14 average.
Twelve months	1	9.00	
Thirteen months	4	8.75	= 8.9 average.
Fourteen months	5	9.00	

These facts he summarizes as follows:

1. A very general correspondence between the age and capacity of the stomach is clearly shown.

2. Starting at birth with a capacity of about one ounce, the stomach increases in size, at the rate of one ounce a month during the first three months, reaching at this time about one-half the capacity seen at one year.

3. From three to eight months its growth is much slower, being on an average half an ounce a month.

4. From eight to fourteen months the rate of growth is still less, being on an average about one-third of an ounce a month.

These statements of course express only averages, and it is to be expected that unusually large, or unusually small, children will be either a little above or a little below these figures. Dilatation of the stomach in healthy infants appears to take place readily.

We may safely infer that the amount of food to be given at a single feeding should not much exceed the capacity of the average stomach at that age, as it does not seem at all likely that any considerable portion of the food leaves the stomach during the few minutes that elapse while the infant is feeding. Dr. Holt also found by experiment with stomach-washing that in infants of one or two months, with apparently good digestion, two hours usually elapsed before all the milk left the stomach; in infants of five to eight months, the time required was generally about three hours. It is evident, therefore, that no feeding should be repeated short of these periods, and it is better in most instances to allow a short interval of rest. *A. D. Blackader.*

ARTIFICIAL IMMUNITY. In the study of immunity from infectious diseases two questions present themselves, viz.: How to explain natural or racial immunity on the one hand, and acquired or individual immunity on the other. In the first place, how is it that in some cases a whole race of animals enjoys immunity from a disease which kills other animals; why is it that certain human races are exempt, or nearly so, from diseases which carry off thousands of individuals of other races? In the second place, how is it that susceptible individuals on recovery from an attack often acquire immunity from a disease? It is clear that where animals are exposed alike to infection, those which do not take the disease must have a natural or acquired power of resisting the attacks of the micro-organisms, and the problem is to find out wherein this power lies. In times of an epidemic the micro-organisms of a disease must surely find

entrance into insusceptible as well as susceptible races of animals or individuals of the same race, in one case doing no harm and in the other producing disease. Why do they find unfavorable conditions for their growth in one case and not in the other? How does the immune race differ from other races, and the immune individual from susceptible individuals?

Two explanations have been offered for the first of these questions, but neither of them has been generally accepted as sufficient. One of these is advocated by Metchnikoff, and bears the name of Metchnikoff's phagocyte theory. According to this theory the white corpuscles of the blood eat up the bacteria, and in animals which have no blood the cells of the connective tissue destroy the bacteria. Metchnikoff [1] bases his theory upon a large number of experiments with different micro-organisms on a great variety of animals. He found that in sponges, mollusks, daphniæ, and earthworms, also in frogs, and in rabbits and other mammalia, the introduction of small foreign bodies, such as carmine granules, or bacteria, was followed by a massing together of the cells, and that these cells either take up the foreign bodies, or surround them. He also verified the observation often made previously, that destructible foreign bodies become dissolved and disappear in the interior of the cells which have taken them up. This theory has attracted a great deal of attention, but has been shown to be inadequate. As pointed out by Ziegler and others the cause of the massing of leucocytes about a foreign body is not due to an intentionally defensive attitude on the part of the animal tissues. Certain substances have the power of attracting leucocytes by so-called chemotaxis,[2] and any foreign bodies which happen to lie in the path of the wandering leucocytes are taken up by these, and may be assimilated. The chemical and physical characters of the tissues and juices determine the direction in which the leucocytes wander, and if the leucocytes are not actively attracted in one direction they wander in the direction of the least resistance. If they are repelled or lamed by the chemical character of a foreign body, they are actually driven away or remain stationary instead of grouping themselves around the foreign body. The idea of an active warfare between bacteria and leucocytes, *i.e.*, phagocytes, must therefore be abandoned. Phagocytosis is a frequent but not characteristic partial phenomenon of inflammatory processes, and not always has the same significance. In some cases phagocytosis results in the destruction of foreign bodies, such as bacteria. In other cases it results in the spreading of the disease to different parts of the body, as in leprosy and mouse septicæmia, where the bacilli grow specially well in the leucocytes, and become subsequently liberated. Phagocytosis must consequently be regarded as merely an incidental process which is often useful, but not always so.

The germicidal properties of the serum of the blood devoid of the cells has also been offered as an explanation of natural immunity. Nuttall, v. Fodor, Buchner, and others have demonstrated the powerful germicidal properties of extra-vascular blood-serum, and there is every reason to believe that the serum in the animal has the same power. This is a most important discovery, but it does not suffice to explain immunity. If natural immunity were to be explained in this way, it is evident that the blood-serum of the immune animals should possess germicidal properties, and the blood-serum from susceptible animals should be devoid of these properties; animals should be immune just in proportion to the degree of the germicidal power possessed by the blood-serum. Such, however, is not always the case. The blood-serum of a susceptible animal often has as much germicidal value as serum from an immune animal. This property of the blood varies, it is true, and in some cases there does seem to be a direct proportion between the extent to which the blood-serum possesses the power of killing the bacteria on the one hand and the degree of immunity on the other.

It is evident from the foregoing that natural immunity is at best but imperfectly understood. On the other hand, artificial or acquired immunity from certain diseases has recently been made the subject of a great amount of experimental research, and many important facts in regard to it have been established.

It is now known that in this kind of immunity the fluid portion of the blood, the blood-serum, acquires the power of neutralizing the disease-producing property of certain micro-organisms. This power of the serum of the blood is acquired on inoculating with cultures of the micro-organisms treated in a special manner beforehand, the details of which are given below. Blood-serum which has acquired this power not only protects the animal in which it is formed, but it also protects or cures other animals when drawn and injected into these. The protective property lies in the serum of the blood and not in the corpuscles.

Immunity that has been conferred in the manner referred to above is also transmitted to the offspring by the mother. Such offspring not only acquire a certain amount of immunity while in utero, but they derive a still larger amount from the mother's milk.

The establishment of these facts is largely due to the investigations of Brieger, Kitasato, and Wassermann, working together, of Behring and his colaborateurs, and Ehrlich. The first of these, Brieger, Kitasato, and Wassermann, emphasize the distinction between infection and intoxication as first made by Koch. Whether the distinction can be sharply drawn in all cases or not, it is important for the understanding of their work to know just what is meant by these terms. The definition below is essentially that given by these authors.

In infection the micro-organisms of a disease gain entrance into the body of a susceptible animal, it may be in very small numbers, and spread and multiply through all the tissues and organs of the animal, plugging up capillaries, depriving the parts of oxygen, and offering a mechanical hindrance to the functions of life. In intoxication the micro-organisms when inoculated in small quantities often produce no disease; they tend to remain more or less confined to one part of the body, their seat of multiplication is localized; they often do not spread to other parts, and are sometimes incapable of growing except on certain tissues; but once having formed a focus they produce a poison which is the cause of the disease. There are two kinds of these poisons found in cultures of bacteria, viz.: ptomaïnes and toxalbumins. The ptomaïnes are crystalline alkaloidal bodies; the toxalbumins are colloidal. The former were obtained first by Brieger, the latter by Brieger and Fraenkel working together, and appear to be the disease-producing constituents of pathogenic cultures. Animals inoculated with them alone show the same symptoms as animals inoculated with ordinary cultures.

The micro-organisms of anthrax produce a typically infectious disease. They find entrance into the body, possibly in very small numbers and only at one minute spot, but if the animal is susceptible they rapidly spread to all parts, so that in one day or less they can be found with the microscope in the smallest drop of blood drawn from any part of the body, and from the smallest bit of any of the soft tissues. The organisms of tetanus, typhoid fever, diphtheria, and cholera, are examples of the bacteria which produce intoxication. They set up a local disease at first, but sooner or later produce specific poisons which cause general intoxication. They are sometimes found in parts of the body remote from the point of original infection, it is true, but not in sufficient numbers or so widespread as to account for the general symptoms of the disease, and moreover, the symptoms are those of profound intoxication. In tetanus the local trouble is often very insignificant and the number of tetanus bacilli, even at the point of infection, surprisingly small, often disappearing entirely before the death of the animal. In diphtheria the bacilli are usually confined to the throat, though they have been found distributed through the blood in other regions of the body. Typhoid fever bacilli are found in the spleen and blood, but are found most extensively in the ulcers of the large intestines. Cholera bacilli are found for the

most part exclusively in the intestines, but occasionally also in the stomach. The bacteria of these diseases are therefore seen to have a tendency to remain localized. The general symptoms are brought about by poisonous products which these bacteria produce. It is not even necessary that these bacteria themselves shall be introduced to produce any of the diseases in question artificially. They may be grown outside the body and their products alone successfully used to produce disease; the bacteria themselves may be killed or entirely removed from such cultures, and still the substance which remains will produce the disease. From the above enumeration of these diseases it is clear that the production of immunity from them is of prime importance in human medicine, and it is precisely in these diseases that recent experiments give the best hope of early practical results.

This difference between infection and intoxication has made it necessary to discriminate between immunity from infection and immunity from intoxication, and for immunity from intoxication the very appropriate term "giftfest," poison-proof, has been introduced. If the micro-organisms of a strictly infectious disease are incapable of increasing in the tissues of any given animal this animal has immunity from the disease in question. Not so with the strictly toxic diseases; for the micro-organisms of these may be incapable of growing in the tissues of an animal, but their toxic products contained in a culture may still be poisonous for this same animal. The animal may acquire the power of preventing the growth of toxic organisms in its tissues, yet be unable to resist the toxic albumin produced outside of its body in cultures. Such an animal resists the inoculation of small amounts of a culture, because the micro-organisms are unable to grow and produce the poison, and there is too little of the ready-formed poison in the small amount of the culture introduced to produce disease. If larger amounts of the culture are introduced, so that enough of the poison already formed is present, the animal dies with all the symptoms of the disease. The animal is not poison-proof, though it may be, strictly speaking, immune from ordinary infection with the micro-organism. But, on the other hand, an animal may be made to resist the poisonous products of a given micro-organism, and still allow the micro-organism itself to grow in its tissues. The animal is poison-proof against the toxic products of the micro-organism in question; the micro-organism has become harmless, or nearly harmless, for this particular animal, and can produce at most slight local trouble, but can no longer exert any general specific action. Consequently, in the artificial production of immunity the object to be attained with infectious diseases is to make the animal incapable of supporting the life of the micro-organisms in its tissues. The object in the toxic diseases is to make the animal capable of withstanding otherwise fatal amounts of the toxalbumins; in other words, to make the animal poison-proof.

The procedure for the production of artificial immunity from the strictly infectious diseases is essentially the same in all cases. It consists in inoculating with attenuated cultures—*i.e.*, with cultures of micro-organisms of weakened pathogenic power—and gradually passing on to cultures of increased virulence, finally using cultures of full strength. Several methods for the attenuation of the virulence of a culture are employed. One method, the practical efficacy of which is doubtful, is to pass the micro-organism through animals of slight natural susceptibility. Pasteur advocated this method to produce immunity in hogs from the so-called swine erysipelas. He found that by inoculating from rabbit to rabbit the virulence of the micro-organisms of this disease increases for rabbits, but, on the contrary, decreases for hogs. Inoculations of the bacilli of hog erysipelas, which have thus been "acclimated" to rabbits, produce slight sickness in hogs, and, after recovery, these animals resist inoculations of cultures of full virulence for about a year.

Other methods of decreasing the virulence of pathogenic micro-organisms are the use of certain chemicals, and of heat, on the cultures. In general, it holds true that all agencies which are injurious to the micro-organisms, if allowed to act for a short time, or if used in relatively small quantities, will produce attenuation. Carbolic acid, in the strength of 1 to 600, deprives anthrax cultures of all virulence without killing the organism if allowed to act on the cultures twenty-four days. Bichromate of potassium, if used in solution of 1 to 1,700 of water, kills anthrax bacilli; if used in more dilute solution, 1 to 2,000 or 1 to 5,000, it weakens the virulence of these bacilli to such an extent that they will no longer produce the disease in sheep, but are still capable of killing guinea-pigs and rabbits. Again, cultures of anthrax bacilli may be attenuated by subjecting them to temperatures between 42° and 55° C. for lengths of time varying from ten minutes to four weeks or more, the length of time varying in inverse ratio to the degree of heat. A combination of heat with the action of chemicals on the cultures has also been successfully used. But whatever method is employed, the object is the same, viz.: to obtain cultures which produce on inoculation little or no disturbance in the health of the animal, but enable the latter to resist more and more virulent cultures, to bring about such a condition that the micro-organisms are incapable of growing in the tissues of the animal. Recent experiments of Brieger, Kitasato, and Wassermann have shown, however, that with anthrax increased resistance, but not full immunity, may be produced in this way. Animals so treated resist inoculations of somewhat weakened but still virulent cultures, but they succumb without fail to inoculations with tissues of animals dead of anthrax. In mouse septicæmia complete immunity can be produced by combining these methods with those described below for the toxic diseases, making the animals so treated incapable of infection, and also poison-proof.

The bacterial proteïds or toxalbumins are unstable and easily destroyed. This might lead to the supposition that they can be as readily destroyed within the animal body as outside, but such is not the case. Many of the chemical and physical means so efficacious in rendering cultures harmless are either inapplicable or powerless in the animals. Some of them, however, give good results.

The efficacy of Pasteur's inoculations for hydrophobia will now probably be universally conceded. The etiology of this disease is still obscure; there is every probability that it is caused by a micro-organism, but this has not yet been discovered. Pasteur found that the poison of hydrophobia is contained in greatest amount, if not exclusively, in the central nervous system, and moreover that the surest way to produce the disease is by subdural application of cerebro-spinal substance from an animal suffering from rabies. Animals inoculated in this way always have violent hydrophobia in from fourteen to twenty-one days. The virulence of the material is weakened by passage through apes, but is increased on passage through rabbits. By inoculation from rabbit to rabbit through forty or fifty of these animals successively, Pasteur obtained a "virus fixe" which had a period of incubation of only seven days, and differed from ordinary "street hydrophobia" not only in the shorter period of incubation, but also in that it produced the disease on subcutaneous injection. A series of exactly graduated virulence was obtained by successive inoculations of the material which had been weakened by passage through an ape. By inoculations with the series so obtained dogs were given immunity. Pasteur subsequently changed this method of attenuation, and has used it for several years upon human beings. The method Pasteur now employs consists in using the dried spinal cord of animals suffering from rabies. It was observed that the spinal cord of such animals gradually loses its virulence if dried at 20° C., and ceases to act if dried for sixteen or eighteen days. Starting with cord that has been dried for fourteen days, the injections are made in more or less quick succession, often several a day, till material of full virulence is used. The injections are made in the abdominal wall above the groin.

Koch prepared a lymph which was successfully used in some cases of tuberculosis. This lymph, or tuberculin, was made by extracting cultures of tubercle bacilli

with glycerin. The cultures were made in glycerin bouillon, and the bacilli which accumulated on the surface of such cultures were skimmed off, extracted with glycerin, and sterilized. Individuals suffering from tuberculosis react in a characteristic manner when inoculated with this lymph, but the expectations in regard to its curative value at first aroused have not been fulfilled. Similar lymph has been prepared from cultures of glanders, and used for diagnostic purposes. This so-called mallein was prepared by Kalming, Preusse, and Pearson, each independently.[3]

The application of certain substances at the seat of inoculation prevents infection. The most potent substances of this kind are the trichloride of iodine and the double chloride of gold and sodium. These substances must be applied shortly after inoculation, they fail to act a few hours later. They also fail when injected at a place remote from the seat of inoculation.

These substances also destroy the pathogenic power of bacteria when put into the cultures, or when mixed with the culture-medium upon which the bacteria are grown. Behring was the first to observe these facts,[4] and he has shown that better results are obtained by using cultures containing the trichloride of iodine than with any other method.[5]

But cultures containing watery extracts of the thymus gland were employed by Brieger, Kitasato, and Wassermann in a number of diseases with satisfactory results.[6] These authors succeeded, by the use of cultures grown in thymus bouillon, or by mixing the thymus extract with cultures, in producing in animals immunity from tetanus, cholera, diphtheria, typhoid fever, erysipelas. A certain amount of resistance was also obtained with anthrax, *i.e.*, animals resisted somewhat weakened but still virulent cultures, but not tissues from animals dead of anthrax. It could hardly be expected that immunity from anthrax could be obtained in this way, as it is a typically infectious, and not a toxic, disease. Immunity from mouse septicæmia could only be obtained by using cultures of the organism in thymus bouillon, and afterward inoculating with old weakened, but still somewhat virulent cultures, *i.e.*, combining the method for the toxic diseases with that for the infectious.[6] There are several theoretical considerations which led to the employment of the extracts of thymus gland. There is a certain analogy between the enzymes or physiological ferments and the bacterial proteids: the former, like the latter, are albuminoid poisons. Gautier, Bouchard, and others have shown that the physiological ferments act as poisons; this being the case, they could not circulate as they do in the blood without injury to the animal unless there be some arrangement for neutralizing their toxic qualities. This arrangement, it is held, probably lies in the protoplasm of the cells of the tissues, and for this reason those organs which are richest in cells and blood seem best adapted to this function. It would appear for this reason that the thymus, thyroid, and lymphatic glands act as purifiers of the blood that streams so abundantly through them, and direct observations go to show that the thyroid gland has the power of destroying this kind of poisons to a remarkable degree, for, as pointed out by Horsley and others, extirpation of the thyroid is followed by symptoms closely resembling those of chronic intoxication, and these symptoms, as shown by Vassale, can be successfully combated with injections of the juice from the thyroid gland of other animals. Transplantations of the thyroid gland in man and animals are also followed by improvement in the symptoms where the transplanted gland grows. The lymphatic glands appear also to possess this quality. They seem to be inserted into the lymphatic circulation for the purpose of arresting poisons contained in the lymph, for it often happens that a local affection spreads to the nearest lymphatic glands and there ceases. It is believed that this power of the glands to counteract poisons consists in the production of specific antitoxins which are given up to the blood on its passage. The antitoxins are supposed to be formed in the animal when the poisons are introduced. If the amount of poison introduced, or formed by the growth of bacteria in the body, is not sufficient to kill the animal, it brings about the production in the animal cells of an antitoxin, and after complete recovery the animal is able to bear larger doses. But in every case inoculations must finally be made with increasing amounts of cultures of full virulence.[5]

In this way the antitoxic property of the blood can be produced, and greatly, perhaps indefinitely, increased by the cautious introduction of larger and larger amounts of cultures, which have been modified by heat,* by the addition of trichloride of iodine or extracts of the thymus gland, or by increasing doses of the toxalbumins themselves.

The latter method has been clearly demonstrated by Ehrlich.[7] Vallet[8] in this connection produced immunity from intoxication with cultures of B. coli communis by feeding rabbits with diluted sewage. It is true that Ehrlich at first used toxalbumins derived from higher plants, and not bacterial proteids, but the analogy is very close between the two kinds of poisons, and Ehrlich's results have been found to agree with results obtained subsequently with bacterial toxalbumins. The substances which Ehrlich used are more easily procured, and the amounts can be more accurately determined than with the indefinite mixtures found in cultures of bacteria, and for this reason the experiments with the former are not complicated by variability in the action of given amounts. The advantage of working with definite quantities is evident, and this is clearly impossible with bacterial proteids till these have been obtained pure. In the one case the effects produced by a given quantity are the same in all cases, in the other the effect has to be determined in every case beforehand, because the amount of toxalbumin varies in different cultures. For this reason Ehrlich decided to study the production of immunity from abrin, a toxalbumin derived from the jequirity bean; risin, a similar poison obtained from the castor-oil bean; and, in a different set of experiments, robin,[9] from acacia bark. Ehrlich found that by feeding mice at the start with biscuits containing much less than the fatal doses of these poisons, the animals gradually bore greater and greater amounts till they could be inoculated without injury with amounts of the poisons sufficient to kill a great number of mice. The mice were made "abrin-proof," "risin-proof," or "robin-proof." In every case the process is specific, an animal which is abrin-proof is not proof against poisonous doses of risin or robin, and *vice versa*. This is also true for the bacterial poisons. An animal that has been made proof against the poison of tetanus is not necessarily proof against the toxalbumin of cholera or typhoid fever.

As stated above, the antitoxic property of the blood of poison-proof animals not only protects the animal itself, but the blood can be drawn and used to protect and even cure other animals. The testimony in regard to this is constantly increasing, and its practical importance is evident. Thus Stern[10] found that freshly drawn blood from typhoid fever convalescents protects mice. G. and F. Klemperer[11] found that blood-serum, and also sputa, from persons that have passed the crisis in croupous pneumonia, possess anti-toxic properties. They also made an extract from the tissues and intestinal juices of a pneumonia-proof animal, and used it successfully on pneumonia patients. Sternberg[12] found that blood-serum from a vaccinated calf neutralizes both bovine and human virus. It must be clear that if it is possible to obtain blood acting as above described it is only necessary to make large animals poison-proof, and use their blood for the prevention and cure of disease. As pointed out by Behring, the possibility of this "blood-serum therapeutics" is now clearly demonstrated, it only remains to obtain large animals in sufficient numbers to put the method into general use; it would also require considerable time to make the animals poison-proof, and a certain percentage of loss would also have to be reckoned upon. In view of any eventual practical utility of

* Vaillard produced immunity from tetanus in rabbits with cultures heated to 60 or 65° C.

the blood-serum therapeutics the selection of the animals from which the serum is to be obtained is a matter of great importance. It would be practicable to use only large animals, so as to get sufficient quantities of serum. It is also necessary that the animals be susceptible at the start. It is true that claims have been made for the inherent protective value of blood-serum from non-susceptible animals, but these claims have not been substantiated. Kitasato has shown that the blood of chickens ordinarily has no protective value against tetanus when injected into other animals, although chickens have natural immunity from tetanus. Still Vaillard[13] has shown that even such animals can be made to furnish protective serum by inoculating them with very large amounts of a virulent culture. Chickens injected with 15 to 20 c.c. of a filtered but not heated culture furnish blood of high protective worth. But it is only blood-serum from animals naturally susceptible, but rendered poison-proof, that attains the highest protective value. So in the different diseases it would be necessary to use different animals. Thus for tetanus horses are the best suited, they can supply a large amount of blood, and are naturally very susceptible. In fact, horses have been used for this very purpose.[14] Tissoni and Catanni, and others, have also reported a number of cases of tetanus in the human being cured with blood-serum of tetanus-proof dogs. The most suitable animals to use for diphtheria are sheep, and they have also been used for this purpose.[15] The more susceptible an animal is by nature the higher the degree of curative value obtainable; and the higher the degree of resisting power produced in the animal the stronger the power of its blood. The value of the blood-serum depends, in other words, upon the extent to which the animal from which it has been obtained has been made poison-proof. The degree to which an animal has been rendered poison-proof is expressed by the number resulting from dividing the minimal fatal dose into the largest amount which the animal can bear without serious symptoms. In animals of the same kind the size of the fatal dose increases with the weight of the animal. The minimum fatal dose is that which is just able to kill an animal of a given kind and size. Thus if two guinea-pigs of approximately the same weight are inoculated, one with .01 c.c. of a diphtheria culture, and the other with .005 c.c. of the same culture, and the animal inoculated with the larger amount dies, while the latter shows very slight symptoms or none at all, the minimum dose of this culture for guinea-pigs of such weight is .01 c.c. If a guinea-pig of equal weight with the two in the example above withstands an inoculation of .01 c.c. of the same culture, this animal is said to have one degree of immunity; if it withstands .02 c.c. it has two degrees; if it withstands 1 c.c. it has one hundred degrees of immunity, and so on. This is Ehrlich's method of expressing the degree of immunity in poison-proof animals. The protective value of the blood-serum of such animals may be expressed numerically, as suggested by Behring and Wernicke, as follows: The smallest amount of blood-serum necessary to protect an animal is taken as a unit and compared with the weight of the animal, and this proportion is used to express the protective power of the serum. Suppose three guinea-pigs are used to test the value of the serum of a diphtheria-proof animal, and suppose one of them receives .5 c.c. of serum to every one hundred grammes of its weight, a second 1 c.c. of serum to every one hundred grammes of weight; the third 2 c.c. to every one hundred grammes of weight, the protective value of the serum would depend upon which of the animals showed marked symptoms of diphtheria poison upon inoculation of a fatal dose. If the animals which received .5 c.c. and 1 c.c., respectively, should die, and the other one showed no marked symptoms, the blood-serum would have a protective value of 1 to 50. If the animal inoculated with .5 c.c. alone was affected the protective value would be 1 to 100—the animal receiving the blood-serum in this proportion not having been affected by subsequent inoculation with a certainly fatal dose. Animals which show marked local or general symptoms on inoculation with a fatal dose are not regarded as having been protected, even if they eventually recover.

The transmission of immunity by poison-proof animals to their offspring has been thoroughly studied by Ehrlich for animals made proof against the toxalbumins of some of the higher plants, those already mentioned, and also in animals rendered proof against bacterial toxalbumins. The observations in the latter case were few in number, but they tally precisely with the observations made in the former as far as they went.

It is conceivable that immunity may be transmitted by the father and the mother both. Such, however, has been found not to be the case. Immunity is transmitted by the mother alone. It is immaterial in any case whether the father enjoys immunity or not. Immunity in the father does not even increase the immunity transmitted by a poison-proof mother.

Immunity in the offspring might be either a purely maternal gift, or it might be brought about by rendering the mother poison-proof during gestation. These are evidently two different things. In the one case, mothers which have attained a fixed degree of immunity would transmit a part of this to the children; in the other, the same process which renders the tissues of the mother poison-proof would act upon those of the fœtus as well. These two means of acquiring immunity must be considered apart.

Ehrlich distinguishes two kinds of immunity, active and passive. In active immunity there is a peculiar adaptation of the animal organism to resist toxalbumins, *i.e.*, the production in the body of antitoxins, and it is characterized by extraordinary stability. In passive immunity there is an introduction of a certain amount of the ready formed antitoxin; as soon as this is eliminated from the body the animal is no longer poison-proof. Thus by the introduction of autitoxic serum into an animal it is possible to produce often astoundingly high degrees of resisting power, but, from the nature of the case, the resistance is limited in time. The ready-formed antitoxin is eliminated in from thirty to sixty days, and as the animal is not given the power in this way to actively renew it, the latter is no longer poison-proof.

Now, the immunity transmitted by the mother is of this kind; she does not transmit the power of actively forming the antitoxins, but merely gives a part of that which is formed in her body. The offspring of a poison-proof mother are poison-proof to a high degree about four weeks after birth, but at the beginning of the third month, or more certainly by the end of the third month, all traces of immunity are gone. By this time the antitoxin derived from the mother has been eliminated, and neither these animals nor their offspring, *i.e.*, the grandchildren of the poison-proof animals, have any resisting power.

The second possible way of producing resisting power in the fœtus, viz., by rendering the mother poison-proof during pregnancy, has not yet been sufficiently tested by actual experiment to be decided upon. It cannot be decided on general principles, for the embryonic tissues may not react as the adult tissues do. The probabilities are that they are not as susceptible to the action of the toxalbumins as the adult tissues, and the production of immunity depends upon this susceptibility. One observation of Ehrlich's seems to show, however, that the fœtus can be given active immunity along with the mother. A pregnant mouse was fed continuously with risin, and the young were risin-proof to a high degree four months after they were born; but the experiment was not beyond the suspicion of error, according to Ehrlich's own statement. Experiments of others in this direction are not convincing, because in all cases the test was made at a time when the young may have still had some of the maternal antitoxin remaining, or, as will be seen below, they may have been deriving it from the milk.

That the offspring of a poison-proof female derive antitoxin from the mother's milk is shown very strikingly by Ehrlich's experiments. Ehrlich found in many cases that the young showed resistance to toxalbumins for a

longer time than could be accounted for by a maternal gift of antitoxin at birth. They are protected after the antitoxin derived from this source is eliminated; so they must derive additional protection from some other source, and this proved to be the milk. Indeed, this in sucklings could be the only source. This is proven beyond question experimentally by the results of "swapping offspring, or the wet-nurse experiment." If the litters of the same age from a poison-proof mother and of an ordinary non-poison-proof mother are swapped around at birth, it is possible to observe, in the first place, just how long the immunity derived from the mother as a gift before birth lasts, and in the second place the degree of immunity acquired by normally susceptible offspring from the milk alone. Whatever resistance is shown by the offspring of a poison-proof mother in this experiment must be due alone to the antitoxin acquired in utero; the milk of the susceptible foster-mother contains no antitoxic properties. Whatever resistance is shown by the offspring of the normally susceptible mother must be derived from the milk of the poison-proof foster-mother. The immunity derived in this way alone from the milk of a poison-proof foster-mother is higher in degree than that derived in utero alone. Offspring of an ordinary non-poison-proof mother derive eight times the resisting power from the milk of a poison-proof foster-mother than the latter is able to confer upon her own children, unless these are allowed to suckle her. An illustration will serve to make this clear. A normal, non-poison-proof female was given four offspring of a highly abrin- and risin-proof mother to suckle; this highly poison-proof female was given the five offspring of the normal mother to suckle. The highest degree of immunity observed in the former case was scarcely 5, the highest degree in the latter fully 40, *i.e.*, one of the offspring of the poison-proof mother that suckled the normal female, barely withstood five times the fatal dose at twenty-one days old; one of the offspring of the normal mother which suckled the highly poison-proof foster-mother withstood forty times the fatal dose at about thirty days old. Another experiment of Brieger and Ehrlich[16] which also gave striking results, was made with tetanus upon a pregnant goat and her kid. The goat was treated by the Brieger-Kitasato-Wassermann method, viz., by inoculations of cultures in beef-tea, with the addition of thymus extract. Inoculations were begun six days before parturition, and continued for twenty-seven days after. The kid was found to be highly poison-proof. The protective value of the milk inoculated into mice was shown to be astoundingly great, 1,600 to 2,400 degrees. The serum of the milk was equally potent, and the evaporated serum had 5,000 degrees potency.

It is evident that in inherited artificial immunity, where the poison-proof mother is allowed to nourish her own young, there are two factors: the antitoxin derived by the fœtus, and, still more important, that obtained from the milk. Now, it is evident that this power of the milk must lie in the antitoxin which the latter contains, and the question arises whether this antitoxin is formed by the milk-glands or whether it is formed elsewhere, and is merely eliminated by these glands. It has been found that the latter is the case. If a normal animal is dosed during lactation with blood-serum from a poison-proof animal, the sucklings acquire typical protection from the milk. Experiments with tetanus on mice showed that great immunity up to forty degrees can be produced in this way in the sucklings. Immunity produced in this way is passive, as would be naturally supposed; but it makes its appearance very quickly, within twenty-four hours after the mother has received the protective serum.

Even normal sucklings which are inoculated with a splinter of wood with tetanus organisms on it, and then allowed to suck a highly tetanus-proof foster-mother, recover even if tetanus symptoms appear.

ASEPTOL (Sulpho-carbolic acid; Sozolic acid) is prepared by mixing sulphuric acid and phenol in chemically equivalent parts. It is a sirupy, reddish-brown fluid. Specific gravity, 1.400. Miscible in all proportions in water, alcohol, and glycerine. It is less poisonous than carbolic acid and has a more agreeable odor. The aseptol of commerce is a solution of varying strength, about thirty-three per cent.; specific gravity, 1.168. It possesses antiseptic properties and is used externally for the same purpose as carbolic acid. It is devoid of caustic properties and is less irritating and not so powerful an antiseptic. A solution of ten per cent. may be generally employed as an antiseptic wash. In diphtheria it is recommended as a local application. It may be given internally, but the official salt, sulpho-carbolate of sodium, is to be preferred. *Beaumont Small.*

ASIATIC, OR EPIDEMIC CHOLERA is an acute infectious disease that is endemic in certain parts of India, and that has during this century advanced out of that country to other parts of the world, where, in its epidemic form, it has produced great loss of life. It is characterized by its great fatality among the communities to which it may be transported, by the apparent ease with which it has been carried from place to place, and by its invariably following the lines of travel in its march from one place to another. It is distinctly a disease of the gastro-intestinal tract, produced, primarily by a micro-organism, and attended with secondary symptoms, due to the absorption of toxic principles elaborated during the development of this micro-organism.

A study of the history of the epidemics that have occurred outside of India will easily demonstrate the facts in regard to the ways by which the disease is transported from place to place.

There is only a difference of degree between cholera, choleraic diarrhœa, and cholerine—the disease is the same in all these forms provided that they are accompanied by the activity of the spirillum of Koch. So far as true cholera and cholera nostras are concerned, there is a very great similarity, or rather there may be, between the clinical symptoms of the two diseases, but the differentiation may be easily made by the isolation of the specific spirillum of the former. The same thing is true in regard to the differentiation of true cholera from an attack of indigestion, which, if severe enough, may take on many of the characteristics of true cholera. Cholera nostras is a seasonal disease and is not transportable, and it has been known for ages. True cholera made its first advance out of India in 1817, and since that time has been seen periodically in Europe. In all cases it has followed the line of travel, and has never been seen to be distributed in any other way. Therefore true cholera never makes its appearance except after other cases have been seen that might excite suspicion, while cholera nostras appears only in hot weather, in sporadic cases, and dies out if the weather becomes cooler.

The period of cyanotic chills, although one of the most

striking in both diseases, gives no special indications for differential diagnosis, for the same thing is seen as an accompaniment of many other diseases, as acute catarrhal diarrhœas, acute poisonings, etc. The prodromic period exists in cholera nostras practically always, but not nearly always in true cholera.

The period of reaction is of importance in differential diagnosis. In cholera nostras it is usually benign—if the patient escapes the violence of the first attack, convalescence is as a rule easy and rapid ; with true cholera, on the contrary, convalescence is exceedingly dangerous—full of pitfalls, and may terminate fatally at any time.

History of Epidemics of Cholera and Their Lessons.—The dispute is active as to whether true cholera existed in India before its appearance outside of its limits in 1817, but the probabilities are all in favor of its having done so ; the especial point that seems to be changed in its nature being that it then seemed to take on the property of migration. Whether this was in reality a new property, or whether it was simply brought to the notice of Europeans by their being first attacked by it, is an unsettled question. There is no doubt, however, of the very great influence exerted upon its spread by the great pilgrimages to the various shrines of India ; nor is there any doubt that the sole home of true cholera—the one place where it is present all the year in an endemic form—is the delta of the Ganges. There are also certain places in India, Indo-China, China, and Japan in which it seems to be present nearly all the time, but it certainly is not endemic in Persia, on the borders of the Caspian Sea, nor in Mecca.

From this one place in which it is endemic, cholera has always been transported to Europe in the steps of the traveller and along the routes of commerce ;—neither wind, moisture, electricity, nor any of the forces of nature have taken any active part in the actual transportation of the disease, although unfavorable climatic and hygienic conditions, of course, may play a favoring part in the development of the disease, after the arrival of its cause.

Epidemics of Cholera.—Cholera has made five appearances in Europe—in 1830, in 1846, in 1865, in 1884, and in 1892. Each one of these appearances was a great epidemic.

There had been also, in 1823, in Astrachan, a small epidemic of cholera, important, because it traced the route that the succeeding invasions would follow. Leaving Persia, where it prevailed in 1822, cholera invaded the southern provinces of Persia, forming the southern shore of the Caspian Sea. After some ravages, it became quiescent during the winter of 1822, to reappear in April, 1823, at Recht. From this city, following the western shore of the Caspian Sea, it crossed the Russian frontier in June, at the little town of Astara. From Astara it reached Lenkoran on the 29th of June. On the 11th of September it was seen at Bakou, and on the 22d at Astrachan, where it soon disappeared.

The First Epidemic.—The epidemic of 1830 had the same origin. Ghilan and Mazanderan, the two Persian provinces before invaded, were attacked in 1829. The disease was quiescent during the winter, but appeared in the spring in Ghilan and in the little port of Enselli, situated several hours' journey from Recht. As in 1822, the cholera followed the western border of the Caspian Sea, and showed itself about the middle of June, 1830, at Salian. Taking here two different directions, on the one side, it appeared at Bakou, Kouba, and Derbent, and invaded Astrachan ; on the other, following the whole valley of the Koura, it advanced toward Tiflis, passing by Elizabethpol, and spreading throughout the whole of the Caucasus. In this way it reached successively the neighboring regions of Astrachan, and advanced up the Volga. On the 4th of August it was at Saratow, thence extending into Russia, and reached the other European States.

This epidemic, by certain extremely interesting peculiarities, demonstrated from the very first the transportability of cholera.

The Second Epidemic.—In 1846, after having reached Salian by a course identical with the preceding, cholera was seen on November 8th in the city of Chemacka, a short distance from Salian. It was in Bakou and at Derbent in December. Forgotten during the winter, it appeared in April, 1847, in the districts of Derbent and of Kouba, and at Tamir-Khan-Choury. From thence it was transported by sick soldiers to the mineral waters of Kisliar. The disease was disseminated among the Calmucks scattered over the steppes near the Volga.

On July 15th it appeared at Astrachan, and advanced at the same time toward Tiflis. From Tiflis it reached Kontais, and was soon carried to Trebizond.

North of Tiflis, the cholera followed the great military road that crosses the Caucasus at the height of 7,000 feet, and toward the end of July it existed at Stavaropol, on the other slope. (It is to be observed that before reaching Tiflis, the cholera entered Persia by the great routes of travel that pass from Bakou, by Erivan, Natchichievan, Djoufa, Ordoubaz, and on toward Tauris. On the one side it attacked the region of the Black Sea, and invaded all its ports ; on the other, it passed through Russia, Germany, France, and Italy.)

A striking thing about these epidemics, aside from the exact places that they attack, is their progress by successive stages—a form of advance that is always the same, and which is a trait common to all the epidemics of cholera that have followed the land route. This second epidemic persisted until 1855.

The Third Epidemic.—The great epidemic of 1865 was the first one appearing by the sea route. It demonstrated that the danger is not localized on the Caspian Sea, but that it is also present on the shore of the Red Sea. Its appearance by this route upset all the doctrines that had been held until that time, and the panic that it produced in Europe resulted in the first conference at Constantinople. It is interesting to follow in some of its phases the course of this epidemic, because its influence has been great. It started from Mecca, having been brought into that city by ships coming from India filled with pilgrims. Toward the end of April it broke out in Meeca and at Medina. The mortality increased very greatly during the three feast days at Arafat. More than thirty thousand of the pilgrims died of cholera, and the progress of the disease showed that *everywhere it accompanied these pilgrims.* Egypt, by reason of its proximity to Mecca, was the first country attaeked.

From May 19th to June 10th ten steamers landed from twelve to fifteen thousand pilgrims at Suez. By false declarations from the captains they were passed at Suez, although the Sydney, an English steamer, had lost a number of eases during the voyage. The first steamer, landing May 19th at Suez, had thrown its dead into the sea. On the 21st, cases appeared at Suez, and among the number were the captain of the vessel and his wife.

June 2d, the first case appeared at Alexandria, and in two months cholera had four thousand victims in Alexandria, and in Egypt, in less than three months, it produced the death of more than sixty thousand individuals. The foreign population emigrated *en masse,* and carried with them throughout the entire world the germs of the disease. Europeans and Levantines, to the number of from thirty to thirty-five thousand, started for all the ports of the Mediterranean, and cholera developed at Constantinople, at Smyrna, at Beyrout, in Mesopotamia, and at Odessa on the Black Sea, and was carried to New York and Guadaloupe by steamers, *appearing in the port at the same time that the steamer landed its passengers.*

Its importation into New York was as follows : The Atlanta, an English ship, left London on October 10th with a cargo of merchandise and forty passengers. The sanitary condition of London was at that time excellent. Reaching Havre on the 11th, where it remained one day only, it embarked 564 new passengers, mostly Swiss, who had all passed through Paris, where, with certain exceptions, they had remained at least a short time, and where at the same time cholera was raging with great intensity. Two German families had stayed in Paris at the Hotel of La Ville de New York, and five days at the hotels of the Weissen-Lamm and Hultgarderhof. Some emigrants that had arrived several days before in these

last hotels had fallen suddenly ill. The steamer sailed on the 12th, and on the next day there was a death from cholera of a child in the family coming from the Weissen-Lamm Hotel. Five other deaths followed on the 14th, the 16th, the 18th, the 19th, and the 22d, in the family that had stayed at the Hultgarderhof.

On the arrival of the Atlanta the surgeon declared 60 cases of cholera, and 15 deaths during the voyage. Two deaths occurred in port, and of the 142 patients sent to the Marine Hospital from November 6th to 19th, 6 died, which makes a total of 23 deaths. The Atlanta was immediately isolated in the lower bay, and after ten days of quarantine all the sick were removed, and, thanks to these measures, New York was preserved.

There were also importations in 1866 by the steamers Virginia and England.

The epidemic of 1865 ceased in 1874, and there was no other case seen in Europe until 1884, although there were interesting manifestations in other countries and on the sea—interesting from the point of view of the transportability of the disease.

The Fourth Epidemic.—The epidemic in Egypt in 1883 was no surprise to those who knew the sanitary condition of the country. Cholera appeared at Damietta toward June 19th or 20th, possibly a little earlier, and its explosion at this time is ascribed, certainly by the French, to the suppression of all sanitary precautions, including quarantine, by authority of the British government. This epidemic at Damietta, increased for about fifteen days, remained stationary for about five or six days, and then diminished just as speedily. It was almost extinct a month after its appearance, having claimed from two thousand to twenty-five hundred victims. The spread of the disease throughout Egypt was manifest and rapid. (An interesting account of how this epidemic reached Damietta is given in Proust's work on the "Defence of Europe against Cholera," Paris, 1892, p. 7.)

Cholera had not yet died out in Egypt, before the news came that it had broken out among the pilgrims to Mecca, and there has been much discussion as to the origin of this epidemic.

In 1884 a number of vessels left the extreme East, and had cases of cholera on board during their voyage; but, by reason of the precautions taken, Egypt and Europe escaped the danger at this time.

The first case of cholera seen at Toulon occurred on June 13th, on the ship Montebello; a second case on June 14th; a third on the 18th, on the Jupiter, near the Montebello; a fourth, also on the 18th, on the Montebello; a fifth, June 20th, on the Alexander, which was also placed near the Jupiter and the Montebello. After the 21st the disease spread through different quarters of the city, and it is thus shown that it did not make its appearance at Toulon in the city, but just outside.

Its importation into Marseilles occurred by the appearance of the first case on June 27th, in a young man, who had three days before come from Toulon. The next case, which occurred on June 28th, was that of a man who lived in the same neighborhood; and from this time onward the disease continued to spread.

In Paris there appeared two cases on the 13th or 14th of July, but the epidemic did not really begin until the 4th of November.

In Brittany the first case was not observed until September 20th, at Concarneau. Other ports were successively invaded.

Algeria was attacked in 1884, and there was a slight recurrence in Algeria and in Tunis in 1885.

Cholera was brought to Italy in 1884 by the Italian workmen, who, to the number of more than eight thousand, returned to their country after the extension of the cholera to Toulon and Marseilles. The Province of Cuneo, in Piedmont, was the first one attacked, on June 27th, and the disease spread successively to different parts of Italy, to Genoa, Naples, Venice, Sicily, and so on.

It appeared in Spain, in the month of August, in the Province of Alicante, and ceased toward the middle of October, reappearing in the middle of February, in the District of Gandia, raging through the month of June to the month of December, 1885, and producing a considerable mortality. It is remarkable that it attacked especially the small towns more than the large cities. The Commune of Aldea de San Miguel, with only five hundred inhabitants, lost more than half of them in thirty-six days.

Cholera also appeared on the Adriatic shores of Croatia, at the end of 1885, and in 1886 on many points of the Austro-Hungarian shore in Istria and in Dalmatia.

The comparison of the mortality in France, Italy, and Spain is interesting. In France and Algeria together there were 13,000 deaths in a population of 39,000,000—1 in 3,000 inhabitants. In Italy there were 35,000 deaths in 26,000,000, that is to say, 1 death in 600 inhabitants. In Spain there were 180,000 deaths, among 17,000,000 inhabitants, that is to say, 1 death in 100 inhabitants. So it appears that Italy was attacked five times more severely by the epidemic than France, and Spain six times more severely than Italy, and thirty to forty times more severely than France.

Much has been said about the immunity of Portugal during the epidemic of 1884 and 1885 in Spain. Many reasons can be brought forward for this, viz., the slight tendency of the Spaniards to take refuge in Portugal, the geographical conditions, and finally, the prophylactic measures taken at the frontier.

In spite of the imperfect quarantine and incoherent measures prescribed by the governments of South America against the vessels coming from Europe, a ship from Genoa, the Perseo, carried cholera to Buenos Ayres, and the disease spread into the Argentine Republic, Uruguay, and Chili.

From 1884 to 1886, a period of three years, more than twenty vessels coming from the extreme Orient to Europe, on passing through the Red Sea and the Suez Canal, had, either at the moment of their departure, or during the voyage, cases of cholera.

The Cholera of 1889, 1890, 1891, *and* 1892 (*the fifth epidemic*).—In 1890 cholera appeared in Irak-Arabi, in Mesopotamia, in Persia, and in Syria, where it had not been seen for almost twenty years. It had been imported into the region bordering on the Red Sea and into Mecca, where it had not been since 1883, and it was observed in Spain, where it had been extinct since 1835.

In summing up what we know of the origin of cholera in Irak-Arabi and in Mesopotamia in 1889 and 1890, the following must be our conclusions:

It is very difficult to admit that the cholera of Irak-Arabi can be attributed to the revival of the old epidemic of 1871, and if this hypothesis be excluded, we are obliged to accept the idea of importation, and it is only possible to think of one portal of entrance, the Persian Gulf, and one source in India, notably Bombay and its environs.

We know from other sources that during and before the appearance of cholera in Irak-Arabi the mortality of this disease in Bombay and its environs reached the enormous number of more than six hundred deaths a week. The condition of the vessels of the British India Company, that alone regularly frequent the Persian Gulf, bring passengers there, and frequently bring pilgrims from India, has been, to say the least, suspicious. Everything points, therefore, to the conclusion, which bears every appearance of truth, that the cholera penetrated into Irak-Arabi through Chat-el-Arab. The importation was performed in this way much more probably than by any other means.

In regard to the epidemic of 1890–91 in Hedjaz, Proust offered the following conclusions to the Committee of Hygiene, which were accepted: 1, The cholera of Cameran was imported by an English vessel coming from India; 2, the cholera of Hedjaz appears to have been brought by the sea route; 3, the pilgrimage to Mecca is a constant menace to the health of Europe; 4, the measures prescribed for the government of the pilgrims to Mecca have not prevented the cholera from developing, and it is therefore necessary to perfect these measures; 5, the prophylactic measures prescribed by the Alexandrian

Conference, at the time of the return of the pilgrims, have this year prevented the disease from gaining a foothold in Egypt and in Europe. There is reason, therefore, for continuing this Conference and for giving it more authority and making it in reality international. There is also reason for increasing the means for isolation and disinfection on the Red Sea.

The epidemic which appeared in Spain in the month of May, 1890, and lasted until the end of November, gave rise to much discussion in regard to its origin that is not yet terminated.

The epidemic of 1892, appearing first in Southern Russia, and thence extending in isolated instances to ports in the north of Europe, appears to be quiescent at the time of present writing, but nearly all sanitary authorities look for a further outbreak during the coming year (1893).

Thus far no cases of cholera, beyond a few isolated ones in New York (*Amer. Jour. of the Med. Sci.*, June, 1892), have appeared in the United States for nearly twenty years.

Transportability and Means by which the Disease is Transported.—The transportability of the disease is demonstrated by, first, the facts in regard to its propagation after it has been imported; second, by the efficacy of certain measures of prevention; third, by the general march of epidemics of cholera; and fourth, by the development of epidemics in the infected localities.

1. *Propagation.*—Brochard, in "Du Mode de Propagation du Cholera," Paris, 1861, reports a very large number of observations favoring the idea of the transportability of cholera, and the number of instances proving this is so great that they need only to be spoken of to be accepted.

An illustration may be taken from the article by Huette, in the *Arch. Gén. de Méd.*, 5th series, vol. vi., p. 571.

In speaking of cholera in Chatillon, he says that the first case was observed in the Faubourg du Puirault, in a workman, thirty-five years old, who was attacked immediately after his return from Oussoi, where he had gone to take care of his parents who were sick with the disease. His neighbors were very soon attacked, and the epidemic invaded the entire Faubourg du Puirault, where it remained concentrated for some little time. Finally, the inhabitants, frightened by the disease, scattered through Chatillon, and the cholera appeared indiscriminately throughout the city. The instance is interesting, because while the inhabitants remained in the Faubourg du Puirault, the disease stayed there, whereas, as soon as they scattered, it spread with them throughout Chatillon.

Another instance, interesting as an example of the transmission of the disease by clothing, is given by the same authority, in speaking of the Commune of Onssoi. Madame Bresson, of the hamlet of Moulineuf, near Oussoi, a precinct free from cholera, received a boarder from Paris June 27th, who on the next day showed the first symptoms of cholera, and died on July 3d. Some days after, a child of this woman was attacked and died on July 13th. On the same day Madame Bresson herself was taken sick, and died on the 17th, after having been taken care of by two neighbors named Sahan and Moret, who died, one on the 16th and the other on the 24th. The husband of Madame Bresson died on July 26th. Madame Burette, who lived in the extreme end of the hamlet, washed the linen of the two women, Sahan and Moret, and was attacked with cholera. In this way, an epidemic was started that carried off eighteen persons in a very short time. Before the arrival of the person from Paris no case had been observed in this hamlet, that had been spared by the cholera both in 1852 and in 1849. Dr. Huette calls attention to the distribution of this hamlet of Moulineuf, which is composed of ten little collections of houses, separated by great distances. No cases of cholera were observed excepting in three of these collections of houses—first, that occupied by the Bresson and Sahan families; second, that occupied by the Moret family; and third, that occupied by the Burette family. The third collection of houses was situated at the extremity of the hamlet. No case of the disease was observed in the other houses, of which the inhabitants had had no connection with these three families.

Proust (loc. cit., p. 165) quotes an occurrence illustrating another series of facts.

In 1854 the French army was collected at Varna, a short distance from the English army. Some detachments remained at Gallipoli, the original place of debarkation. There was, besides, a small Anglo-French force of occupation in the Piræus, and also some detachments at Constantinople. The armies were reinforced practically every day by new arrivals. The sanitary condition was satisfactory in all respects. On July 5th, the packet Alexandre arrived at Constantinople, having left Marseilles on June 26th with five hundred men of the Fifth Regiment of Light Infantry, coming from Montpellier, and having passed through Avignon, where cholera was raging. It appeared on board, and three men died during the voyage to the Dardanelles. Four cholera patients were landed at the Piræus, where the cholera broke out immediately, and made great ravages. The troops were disembarked at Gallipoli, where two new cases of cholera were immediately sent to the hospital, and the ship, having only a few passengers on board, sailed for Constantinople, where a quarantine was imposed on it. On the other hand, it appeared that previous vessels sailing from Marseilles had already suffered from cholera, and that one of them had landed a patient in the military hospital at Constantinople. On July 15th, after new arrivals of cholera patients, the disease spread at Gallipoli, and there appeared in the military hospital of Constantinople a choleraic focus. Fauvel, struck by the danger, proposed, and had adopted by the Council of Health at Constantinople, a momentary interruption of the communication between Gallipoli and Varna. The measures prescribed were not executed, and in spite of the insistence of Fauvel before the Marshal de Saint Arnaud, many ships sailing from Gallipoli passed the Bosphorus, and went directly to Varna, where free pratique was accorded them. Cholera then broke out in the army among the newly arrived soldiers and in the hospital. On August 5th the epidemic was violent at Varna, especially among the troops sent into the Dobrudscha. The English army was invaded, having the epidemic on board the fleet. In the Crimea, the epidemic, helped on by the arrival of the fresh troops, continued until 1856.

The importation of cholera into Constantinople in 1865 equally deserves to be spoken of. Constantinople was in an excellent sanitary condition when the frigate Moukbiri-Sourour arrived from Alexandria, on June 28, 1865. She had passed more than five days on the voyage, and therefore, in accordance with the rule that then held, free pratique was granted her, the surgeon having declared that there had been no illness during the voyage; but this declaration was false. The evening of June 28th there were landed from this frigate twelve sick persons, of whom one was attacked with cholera, who died during the night, and eleven were affected with cholerine. It was learned on the next day that during the journey from the Dardanelles to Constantinople two choleraic bodies had been thrown into the sea. On June 30th nine other cases were landed. The ship was sent into quarantine at the mouth of the Black Sea. The patients were transported to the Marine Hospital, near the arsenal, and here one special circumstance should be noted. The road that went from the landing to the hospital being opposite, it was necessary to carry the sick past the barracks occupied by military workmen in the arsenal, and the first indigenous cases of cholera occurred among these workmen, and on board a corvette that was near their barracks. On July 3d one of these military workers was received at the hospital with a choleraic diarrhœa, and on the 5th presented all the symptoms of cholera. That same day a new case was furnished by the workmen, and another on the corvette spoken of above. The barracks were then vacated, and the workmen were placed in tents on the heights of Okmeidan; nevertheless, the disease continued to rage among them, and among the ships collected before the arsenal, and it attacked on the one hand the guard in the interior of this establishment, and on the other the workmen at the

Ministry of Marine, situated very near the barracks of the military workmen. On July 8th two cases occurred outside the arsenal, and from July 10th the epidemic commenced to invade the quarter of Kassin-Pacha, near the arsenal, and inhabited by the workmen of whom we have spoken. It then propagated itself throughout the city.

One more instance of the importation of cholera may be given, as illustrating that a single case, carried a great distance by rail, may give rise to an epidemic.

Toward the end of the month of August, in 1865, cholera suddenly broke out at Altenburg, in Saxony, in the centre of Germany. The first case was that of Lady E——, who had left Odessa on August 16th, and had arrived at Altenburg on the 24th, without having stopped on the journey. She travelled with a child of twenty-one months old, who was affected with diarrhœa. She went to her brother's, and sent for a physician to see her child, whose diarrhœa had become very severe. This woman, who was meanwhile well, said that at her departure from Odessa there had not been in that city any disease; but this was an error, for some cases of cholera imported from Constantinople were already in the hospital in the lazaret, and, the day after the departure of this lady, cholera appeared at Odessa. She said also, that having embarked to go up the Danube, everybody appeared to her to be well on board, although the vessel had passed by certain localities where cholera was raging; however that may be, three days after her arrival at Altenburg, on August 27th, and the very same day that the physician had visited her child, this lady fell ill, and the next day the physician recognized all the symptoms of Asiatic cholera. She died on the 29th. On the same day, in the same house, her sister-in-law was attacked, and died on the 30th. The child died on the 31st. From this house the cholera spread into the city and suburbs. The family of a workman, who died on September 13th at Altenburg, carried the disease to Werdeau, and the house occupied by this family was the point of departure of another epidemic that carried off two per cent. of the entire population of the city.

2. *The Transportability of Cholera is Confirmed by the Results of Restrictive Measures.*—We see always that a rigorous sequestration and a rigorous interruption of communication by land or sea, if that be possible, results in preserving certain places or certain countries, and in these facts is a powerful argument against any idea of the transmission of cholera through the air.

In 1867 Messina and the whole of Sicily were entirely free from cholera, and yet vessels coming from infected countries daily passed through the narrow Strait of Messina. And again, during the epidemic of 1856 at Constantinople, the scholars of the Military School, to the number of five hundred, were rigorously sequestrated in the establishment, and escaped the cholera that was raging in the neighborhood; and events that occurred at the lazaret of Fort Genoa, in Algeria, in 1884, demonstrated also the efficacy of isolation in order to prevent the transportation of the disease to the neighboring cities.

3. *Transportability as Shown by the General Progress of Epidemics of Cholera.*—If we look at epidemics as a whole, we see that they always follow the course of human currents of travel. It is in the East, or in the countries bordering upon Europe, that we can best follow the development of this law, because in such places the routes are less frequented, and the demonstration is more striking. In order to pass from Persia into Russia in any way except by the great line of travel passing through Erzeroum, Tauris, and Natchischevan, there are only two ways—that over the Caspian Sea, and the land route that follows the western shore of this sea. Both of these routes pass by Recht, Astara, and Lenkoran, and end both of them at Bakou, and in the same way cholera, in the epidemics of 1823, 1830, and 1846, always and invariably passed through Recht, Astara, Lenkoran, and Bakou. At the latter city the land route splits on the north. It continues to follow the western border of the Caspian Sea, and passes by Derbent, and reaches Astrachan exactly as does the sea route, and we have seen cholera at every one of its appearances, in 1823, 1830, and 1846, pass over this same line, passing by Bakou, Derbent, and Astrachan. In 1823 it stopped at Astrachan, while during 1830 and 1846 Astrachan was only one of the steps of its invading march.

The second line of travel passes over the Caucasus. It leaves Bakou, passes by Tiflis, and follows the Caspian Sea to the Black Sea. The point of departure from the Caspian Sea is Bakou. The point of arrival on the Black Sea is Poti, or Trebizond. The epidemics of 1830 and 1846 divided, following both of the two routes that have been spoken of. One current followed the border of the Caspian Sea, another crossed the Caucasus.

This progress of cholera, always following the same lines, is a striking illustration of the law formulated. It always follows the human currents, in the steps of the traveller. It is imported by man alone, and precisely the same point is shown if we follow the successive steps of the epidemics that have travelled by the sea route.

As an illustration, the epidemic of 1854 in the Crimea was due to vessels coming from Marseilles, and carrying troops from an infected country. Cholera appeared successively at every one of the points where these vessels touched. They landed at Messina, and Sicily was invaded. They touched at the Piræus, and Greece was attacked. They stopped at Gallipoli, and cholera appeared at Gallipoli. Constant communication was being held between Gallipoli and the Dardanelles, Constantinople, and Varna. Cholera developed at all three places. The same was shown in the progress of the epidemic of 1865. It must not be supposed, however, that the assertion is made that cholera took the special direction from east to west; on the contrary, it radiated from India in all directions—north, south, east and west—according to the ease and number of the means of communication.

4. *Transportability as Indicated by the Evolution of Epidemics in Infected Localities.*—Many examples of this may be quoted, among which are the following:

In Constantinople it is possible to trace out the successive extension of the disease up to the time of its general diffusion. At Constantinople it manifested itself first at the arsenal, where it had been carried by the sick who were landed from the ship Moukbiri-Sourour. From the arsenal it reached the neighboring quarter of Kassin-Pacha, and then a few cases appeared in different parts of the city, for the most part of persons who had fled from the quarter first attacked. Up to July 16th the total of the deaths from cholera in the entire city, except those at the Marine Hospital, reached 130, when suddenly it was learned that the disease had broken out with violence at Eini-Keni, a village situated on the Bosphorus, twelve or fifteen kilometres from the quarter where the epidemic had begun. It was established that the first case of cholera had appeared on July 11th, in a Turkish café, in a workman coming from Kassin-Pacha; that the next day many of the individuals who frequented this café fell ill, and two died; that during the following days the disease was propagated in the quarter until the 16th, when, after the occurrence of several deaths among prominent families, a panic seized the whole population of the village, who fled in all directions. Mussulmans, Greeks, Armenians, and Jews fled into other villages and quarters of the city which were then unaffected, where they transported the disease. The Jews in particular, who had been the most seriously attacked, and who carried with them their soiled clothing and their dead, became the especial propagating agents of the disease. At Koustoundjouc, at Kas-Keni, and at Balata, the epidemic broke out immediately after the arrival of these fugitives. From this moment dates the generalization of the epidemic. It is not necessary to add other examples. The same thing is shown in the history of every local epidemic that has been intelligently traced.

It has been opposed to this idea of the transportability of cholera that sometimes a restrictive intercourse failed to arrest the progress of the disease; but in all these cases the measures were either tardily employed, or applied without scientific rule. Others have spoken of the immunity of countries which had not protected themselves by any sanitary measures. The answer to this is

the question, whether cholera, although it is a disease capable of spreading by infection, must, therefore, be possessed of a method of forcing this infection. And, in conclusion, no matter what the differences of opinion are, the law of transportability remains absolutely established by all the facts yet obtained in regard to cholera.

Methods of Transportation of Cholera.—In a consideration of the question of the method of transportation of cholera, we are to look at two principal points, the agent of cholera, that is, the organism of the disease, and second, the medium.

The agent of cholera is unquestionably a bacterium, having India for its origin. It extends itself, and reproduces itself indefinitely, and many media serve as vehicles for its transportation throughout the entire world, but this choleraic agent would be wholly powerless if it did not encounter favorable conditions for its development. The medium, therefore, is indispensable to its power, and this favorable medium is made up of certain telluric conditions, the surroundings, and so on. So far as the methods of transportation of cholera are concerned, therefore, we have to consider more the medium in which it appears than the cause of the disease itself. Fauvel has expressed this truth as follows: "That a fire is not proportionate to the spark which gives it birth, but to the combustibility and mass of the material that it encounters." So, frequently, a few cases, or one only, as at Altenburg, are sufficient to produce the explosion of an epidemic.

The clinical consideration of the means of transportation of cholera is to be made under the following headings:

First, the transportation by men attacked by cholera, and the rôle played by the closets that have received choleraic excreta. A person arriving from an infected place is always necessary for the beginning of an epidemic. In other words, man himself is the most powerful agent for the spread of cholera, the specific micro-organism being found, as has been demonstrated by innumerable experiments, in the excreta. Washerwomen have been attacked by the disease after washing linen soiled by evacuations, while others, who had simply touched this linen, also contracted the malady. Budd relates (quoted by Hirsch in *Schmidt's Jahrbucher*, vol. xcii., p. 255) that in 1854 a person affected with cholera arrived in an English factory of 645 workpeople. There followed 144 deaths from cholera in five weeks. The disease developed solely among those who made use of the closets where choleraic dejecta were deposited. Instances of this kind can be multiplied almost indefinitely.

Second, the transportation by means of choleraic diarrhœa. As illustrations of this, innumerable instances might be quoted, especially that mentioned by Budd in the reference given above. A person sick of diarrhœa came into the midst of a perfectly healthy population in a colliery, and died. Diarrhœa became general, and seventeen persons contracted cholera. The case of Dr. Alexander, in the *Gazette Médical* for 1849, is also an illustration of this point. There was not at Hamel, a village twenty-five kilometres from Amiens, any indication of cholera, when, on April 4th, from Paris, where cholera existed, there arrived a soldier sick with diarrhœa. He was received into his parents' house where he remained three days. On the 14th he went to the Hôtel-Dieu, and the same day his brother, who had come a number of times to see him, was attacked by foudroyant cholera, and died in twelve hours. His wife died three days afterward. The father, who had shown some symptoms of cholerine, was attacked with cholera on the 11th, and died on the 15th. Another son of this man, seventeen years old, and a child of four years, his grandson, were attacked with cholera, and got well. The father-in-law of the brother who had taken care of him and his daughter were attacked by cholera, but recovered. A child of eleven years, who was often at the house, and whose parents had taken care of the same brother and his wife, was attacked on the 14th, and died the following day.

Third, can the bodies of persons dead of cholera communicate the disease? Although the evidence seems to point toward this being a possible danger, it is not a serious one in civilized countries.

Fourth, can cholera be transported by healthy individuals? This must be answered in the negative. The facts quoted that seem to show that this can be so, must be explained by supposing that the individuals who were believed to be entirely well were in reality sick of a choleraic diarrhœa, or else that they carried clothing or linen soiled with choleraic material.

Fifth, can cholera be transported by living animals? Animals are not susceptible to the disease. A certain number of experiments have succeeded in producing cholera in animals, but with great difficulty. There is no fact to support the supposition that animals can carry the disease, either on the skin or hair.

Sixth, the transportation of cholera by means of clothing, personal effects, and so on. The disease cannot be so transported unless these materials have been contaminated by cholera dejecta. This, of course, is an exceedingly important point, for if soiled, the material may be dangerous; if not soiled, there is no danger at all, even if it comes from cholera centres. It is of equal importance to know whether contaminated objects have been packed up, or exposed to the air. A contaminated object exposed to free air for a definite time loses its power of transporting the virus. The Conference of Constantinople considered that a very short time was sufficient to do away with all danger, and recent bacteriological research has wholly confirmed this opinion. On the other hand, contaminated objects that have been packed up and kept closed from air retain their virulence for a greater or less time, as may be shown by many instances.

Seventh, can cholera be transported by merchandise? Although merchandise imported from India, whether to Suez, or directly to Europe, has never been known to transmit cholera, this method of transportation is not absolutely impossible, and many of the materials brought from India—cloths, and so on—retain in their interstices a confined air that certainly might preserve and transport for a great distance the contagion with which they may be impregnated; but although this is a possibility, it is not probable, and the Conference of Constantinople unanimously accepted the absence of proofs of the transportation of cholera by merchandise, while it admitted the possibility of its being done, under certain conditions. Since that time, Zehnder, the Swiss delegate to the Vienna Conference, in 1874, cited facts in favor of the danger of rags in transporting contagion (see the report of the International Sanitary Conference of 1874, page 272). But at the Conference in Rome, in 1885, Koch disputed the interpretation that had been put upon these facts.

Eighth, water is perhaps the most important agent in the spread of cholera, and evidence to this effect was obtained long before the discovery of the cholera spirilla. J. Simon brought out some facts in England showing it. At London thirteen deaths out of a thousand inhabitants occurred among those whose houses were supplied with river water in the neighborhood of the sewer. Tested at this point, the water yielded forty-six grains of solid residue to the gallon. In other houses in the city that were in the same hygienic condition, but not supplied with this water, the mortality was only three and seven-tenths in a thousand, but the water which they used had been taken from outside the city, and yielded only thirteen grains of solid residue to the gallon.

At Halle, Delbruck noticed that in prison, where the epidemic had developed very largely, the wells communicated with the drains. At Brachsted the epidemic arrested itself just as soon as a suspected well was closed. Delbruck explained the less intensity of the epidemic of 1867, compared with that of 1866, by the fact that the carrying of the water had been modified. Water was furnished almost pure in 1867, while up to the autumn of 1866 the conduits carried the water from the Saale through a region where all the discharges of the city were scattered. Ballot also spoke of the influence of impure water on the spread of cholera in Holland.

Snow, in England, and innumerable other writers in Europe, India, and America, lay the greatest possible stress upon impure water as the special means for the conveyance of the infective agent of cholera.

The contamination of water played an extremely important part in the extension of cholera in Egypt in the epidemic of 1883. The Mussulman population of Egypt bathe very frequently, but they are not careful about the water that they use for drinking. At Damietta the water is exceedingly foul upon the points of the Nile from which the water-carriers fill their water-casks, and just at these places are the special spots selected for bathing. The houses along the bank discharge their foul material directly into the river, and drains carry to it discharges from other houses, and from the mosques. According to Koch, these mosques play an extremely important rôle in the spread of cholera. The German cholera commission was able at Damietta to examine a number of mosques, the description of the arrangement of which is as follows: Only that part of the mosque that is directed toward Mecca is used for prayers. At the other end is an open space, in the centre of which is a tank for bathing, and sometimes this water remains several weeks without being changed, and surrounding the basin are a series of urinals and closets. The discharges from the whole are passed into the Nile, so that it is not strange that the infected material should be transported by such a water-supply.

The epidemic of 1884 furnished new proofs in favor of the spread of cholera through the agency of water. Messrs. Marey, Brouardel, and Thoinot especially insisted upon this point. Marey, at the sitting of the Academy of Medicine, October 14, 1884, said: "Among the influences that can cause the spread of typhoid fever or cholera there is one that by its intensity dominates all the others—that is the contamination of public water-supplies." If a number of epidemics of cholera be studied, it can be determined, in effect, that cholera easily follows watercourses; that it is especially along small watercourses that it is propagated, is most frequent and striking. In order to explain this, there are but two hypotheses that are possible.

First, brooks, torrents, or rivers flow in valleys that are often narrow and shut in, and the villages found there often can have no communication except with each other. When one is attacked, it is a perfectly simple matter that the others should be also in their turn. This explanation is very plausible; for certain cases, and some epidemics, can be explained in no other way. The great rivers, the large watercourses, along which are scattered regions attacked by cholera, serve for the propagation of this disease, like the great roads of travel, in this way only, that they are lines of communication frequented by travellers.

Second, water is certainly a propagating agent of cholera. It is the water of a torrent, a brook, or a small river, contaminated in one part of its course, that transports the disease to the inhabitants on its borders that drink of the water, and innumerable instances can be brought forward to illustrate this point also.

Proust (loc. cit., p. 216) speaks of the choleraic agent having for its vehicle of transportation either the air or the water, but the evidence in favor of the air as one of the transporting agents of cholera is nothing, and the weight of scientific evidence of late years militates against such a means of transportation. Altitude seems to have but slight influence upon the development of the disease up to a certain point, although Farr (in the Registrar-General's Report on the Mortality of Cholera in England, London, 1852) has attempted to demonstrate that the mortality from cholera was in inverse proportion to the elevation. The objection to this is, that the less frequent occurrence of cholera on the most elevated points may be due to the fact that the less accessible points are more thinly inhabited.

Moisture, taken in connection with the subsoil water, is a favoring cause of the greatest importance, and observations in this direction have furnished the basis for Pettenkofer's theory of the connection of subsoil moisture with cholera.

The development of the epidemics of 1836 and of 1854 seemed to coincide with the period of greatest diminution of the subsoil moisture in Munich, and therefore the choleraic contagion with which the soil is impregnated appears to disengage itself more easily. Hirsch reached a similar conclusion. Kreuzer, in 1855, at Vienna, and again Pettenkofer, at Munich, observed the same facts. Pettenkofer's theory differs from others, in that, putting aside the chemical composition of the earth, he attaches a special importance to its physical characteristics, its density, its porousness, etc. He considers that the condition of the subsoil of localities and of houses plays a rôle of special importance in the propagation of cholera, and upon this special cause he places the development of an epidemic, after an importation from without; and, studying almost exclusively the physical condition of the region, the compact or porous condition of the subsoil, he considers that not only the primitive earth, and the soils of the transition period, but also the secondary formations, produce immunity when they are exposed to air in the condition of rocks. On the other hand, every porous soil that is susceptible of imbibition can become easily impregnated with fluid, or with gas, and vegetable earths as well as silicious earths, may form "fat," always moist, lands, throwing out continual moisture about them, favoring the diffusion of the germs of cholera. Where the soil is made up of a compact calcareous rock, cholera never becomes epidemic, and a few cases observed in such situations as the result of importation, do not propagate the disease.

Pettenkofer's theory has two points that must be distinguished from each other.

First, the nature of the soil. The soil must be porous, easily permeable, and also easily impregnated by liquids and gas. This condition is a permanent one.

Second, the level of the subsoil moisture. This level being movable, the effect is variable; when subterranean waters have reached the maximum of their elevation, there is neither decomposition of organic materials, nor throwing off of miasms. If the subsoil moisture descends to a lower level, putrefaction begins, the miasmatic vapors are thrown off more intensely, and just at this time the epidemic reaches its greatest development. This second point of his theory, certainly an ingenious explanation of certain cases, appears to be much more hypothetical than the first, the question of the porosity of the earth.

To sum up, Pettenkofer's theory, while it scarcely has the value ascribed to it by him, certainly seems to be a partial explanation of the propagation of cholera by means of the porosity and moisture of the earth.

Ninth, atmospheric conditions play a not very important rôle, although the influence of season is manifest, and apparently storms sometimes seem to aggravate considerably an epidemic.

Somatic Conditions.—Race or nationality has no influence upon the development of cholera. The special influences favoring it are those of misery, fatigue, cold, and depressing mental conditions, which, by diminishing the resisting power of the body, render it more susceptible to the influence of the epidemic. Collections of human beings, in other words, agglomeration, plays a very considerable rôle in the propagation of epidemics; so also do methods of transportation. Railroads are often the means of propagation, as was the case in the instance of Altenburg, quoted above. The epidemic of 1865, in Paris, was started by a woman who left Marseilles, with a choleraic diarrhœa, and was attacked with cholera upon her arrival in Paris. Transportation by caravans does not give much chance for the spread of the disease, when the distance passed over is of great extent; in fact, a great desert is the best of all obstacles to the propagation of cholera. In ships is most often found united the conditions of crowding and confinement favorable for the development of the choleraic agent.

Proust appears to believe that these elements do not have much potency if the entire ship's company come from the same infected region—in other words, have

acquired an immunity in a choleraic focus; but if the ship's company has received a partial renewal, if new persons have come on board among the acclimated passengers, cholera finds a new favorable medium for attack, and, if aiding circumstances appear, the ship may become the centre of an intense epidemic. He goes on to speak of this "law of accustoming," in what takes place in armies, the great fairs, and the pilgrimages, for when cholera is carried into these great collections, if the mass of people have not undergone the "choleraic acclimating," the explosion of the disease is rapid, and the mortality considerable, but only continues for a few days, and ceases soon. The Crimean War furnishes an example of the rapidity of development and intensity of the disease among vessels free from the choleraic influence.

At the commencement of April, 1855, there reached Constantinople from France, fifteen to twenty thousand troops, made up in part of the Imperial Guard. These troops had not, during their voyage, a single case of cholera among them. They camped on the heights of Masslak, in an extremely healthy situation, and at that time there were in the city of Constantinople but very few traces of cholera. The rolls of the French military hospitals gave only fifty-three cases during March, and the roll of April 11th showed none. In the Crimea the cases of cholera were also very few, and nevertheless the troops were hardly settled at Masslak, when, on the night of April 14th and 15th, cholera broke out among them, and a severe epidemic followed.

Fauvel ("Memoire lu à l'Acad. des Sciences," Paris, 1883) sums up this question of immunity in the following propositions:

"1. The ports of India that are the seat of endemic cholera are never the scene of a great epidemic.

"2. This fact relates to the general, but not absolute, immunity enjoyed by the native population of these parts.

"3. This immunity does not exist in the endemic localities for strangers who are in a condition favorable for contracting the disease. These are especially the Mussulman pilgrims who come to Bombay to embark for Mecca.

"4. The epidemics of cholera that develop in India, in the regions where the disease is not endemic, come from the places where it is endemic, and are favorable for attacking the Hindu pilgrimages.

"5. The epidemics observed among the pilgrims to Mecca can also be traced to the localities where cholera is endemic.

"6. A severe epidemic of cholera confers upon the country or upon the locality which it has attacked a more or less complete immunity, which is more or less durable, and of which it is impossible to formulate the law for Europe, but which in India appears to last for a number of years.

"7. In the Hedjaz, and in the sparsely populated parts of Arabia, cholera has but a feeble tendency to propagate itself among the native population.

"8. The fact of the existence of a great epidemic of cholera in any country whatever is a proof that cholera is not there endemic."

To sum up, new scientific facts bear upon the question of immunity and make them clear upon a side hitherto unknown. The etiology and prophylaxis, in especial, of cholera receive from these facts new indications, and these facts also appear to be the expression of a law that includes an entirely different category of infectious diseases, which leave after them an immunity of a greater or less extent."

Period of Incubation.—The question of the period of incubation of cholera gives rise to a great deal of discussion. It appears, however, that in the immense majority of cases a period of a few days is sufficient for the incubation, and that sometimes this may require only a few hours. This fact is easy to observe if the beginning of the disease in a city or upon a ship be studied.

The Cholera Conference at Constantinople concluded as follows: "That all the facts cited in regard to a period of incubation longer than a few days are based upon cases that are not conclusive, either because the premonitory diarrhœa was comprised in the period of incubation, or because the infection could have occurred after the departure from the infected locality. The following is an instance:

On November 3, 1848, upon the ship Swanton there were two hundred and eighty-nine emigrants for New Orleans, and the cholera did not break out on board until November 25th,—that is to say, the twenty-third day of the voyage,—and occasioned thirteen deaths. A certain number of these emigrants came from points in Germany where the cholera existed. This long period of incubation can be explained upon two hypotheses: either the passengers had with them clothing soiled with choleraic materials, which, placed in a confined air, could transmit cholera; or certain of the individuals embarked might have been affected at the time of their embarkation with a diarrhœa that might later have developed into true cholera. The duration of this premonitory diarrhœa has been much discussed, and in general it has been concluded that it does not last more than three days, and when it does pass this period, it is rarely prolonged beyond a week, and that therefore an individual isolated from all sources of contamination, and in whom the diarrhœa should be prolonged more than eight days after this isolation without presenting any characteristics of cholera, could be considered non-choleraic. But Griesinger among others dissents from this opinion, and declares that the period of incubation of cholera may be much longer. Bacteriological examination is the only method of settling the question.

Description of the Disease. — Asiatic cholera, in individual cases, has no marked characteristics distinguishing it from similarly violent attacks of "cholera nostras;" the only absolute method of making a diagnosis in single cases is by the discovery of the spirillum of the disease and its identification. In general, an attack may suddenly develop, its onset being marked by great uneasiness, repeated discharges from the bowels, followed by syncope. This attack may overtake the victim while walking on the street in apparently good health. It is often preceded by a state of vague suffering, rapid prostration, deep colicky pains, anorexia, sometimes a diarrhœa, profuse sweats, disturbance of the senses, and more or less of retardation of the pulse. After the development of the disease the symptoms follow each other in such a way as to allow of a division into two distinct periods.

First Period.—This is marked by an increase in the number of dejections and acts of vomiting; a flux is established which is at first serous or slightly bilious, and afterward becomes "choleraic." This term is used to designate those characteristic discharges of cholera which are liquid, whitish, grumous, sometimes resembling unclarified whey, sometimes a decoction of rice or oatmeal, and sometimes thickened meal, and nearly clear, which emit an insipid spermatic odor, and sometimes present traces of blood or bile. These evacuations are rarely absent, often continuing to the termination of the disease. Burning thirst, pain in the epigastrium, and prolonged hiccough are usual accompaniments. Intense cramps of the limbs occur, particularly in the calves of the legs; the muscles are often in a state of tonic contraction. Spasmodic movements, as involuntary flexion and extension of the fingers and toes, may often be seen. The pulse is very feeble, often imperceptible. The features are altered, trembling and great agitation come on, the pulse becomes suppressed; bluish spots appear, first upon the extremities; the skin becomes blue or black almost everywhere; the nails are livid and almost black, the fingers wrinkled, and the genital organs retracted. The volume of the body diminishes rapidly and perceptibly; the eyes sink in and are dull, with a bluish circle surrounding them; the conjunctiva fades, respiration is slow and feeble, the breath cold, and the pulse is reduced to a mere oscillation. The secretions are arrested, especially the urine, the voice is reduced to a whisper, the nose is cold and—rarely—gangrenous, the cornea is flattened and puckered; spots of blood appear on the sclerotic, viscid sweat on the face and limbs; the intellect

becomes obscured, respiration is embarrassed, hiccough commences, and death follows, in the midst of an apparent calm. This is called the *cold*, *livid*, or *asphyxic* period. When patients escape death in this stage they enter upon the

Second Period.—In this the coldness ceases to increase, warmth returns, the pulse improves and gradually becomes febrile, the face regains color, the eye becomes animated, and a general reaction occurs.

If recovery is to be easy and rapid, vomiting becomes less frequent, the diarrhœa remains, but the discharges no longer present the appearance peculiar to the disease; the secretion of urine returns, nausea, thirst, and pains in the stomach cease to be felt, the pulse becomes regular, and convalescence begins.

If reaction is incomplete, the cold stage returns with renewed severity, or, on the other hand, if reaction be too severe, such accidents may occur as apoplexies, spasms, convulsions, local congestions and inflammations, and occasionally latent pneumonia. Stupor is sometimes present, with some of the signs of the last stage of typhoid fever. Swelling of the parotid glands and various skin affections, as roseola, urticaria, erythema, erysipelas, etc., may appear toward the close of the disease.

The average duration is from one to three days, but sometimes death occurs in less than six hours, and is occasionally delayed a long time—in one case for fifty days.

Complications and Secondary Affections. — Complications are rare, and apparently accidental; among them peritonitis, jaundice, gangrene, œdema of the lungs, erysipelas of the face, abscesses, ulcerations of the eyelids, and aphthæ may be mentioned as of occasional occurrence. Secondary affections are, however, very common. They may consist of gastro-intestinal inflammations—immediate or occurring after some days of convalescence—or of affections of the respiratory organs. In other cases, persons who have apparently escaped the accidents of cholera have a secondary fever, described as of a typhoidal type —dry skin, tension and tenderness in the epigastrium, jactitation, dry tongue, bilious stools, and chills. Various skin eruptions occur, and temporary albuminuria has been observed following an attack of cholera. The most grave of the secondary affections, however, are those which affect the nervous system. The cerebral congestions during reaction are, in some cases, followed by a typical meningitis with trismus. Rayer's "État Cérébral cholérique" includes a group of phenomena distinct from those of meningitis, which supervene upon the cold stage; the skin is cold, the pulse feeble, the head heavy, the countenance stupid, and sometimes the cholera tint remains. Another affection is a sort of non-febrile delirium, lasting for two or three days, and the spasmodic contraction of the forearm which occurs during convalescence. True intermittent febrile attacks, with initial chills, occurring every day during reaction, have also been observed. All these affections are, for the most part, more rapid than when occurring in an individual previously healthy.

Course, Duration, and Termination.—If death does not occur during the algid stage, a peculiar transformation in the disease takes place and *reaction* sets in. This reaction varies in different cases, being slow and tedious in some, and abrupt and rapid in others; its course is not essentially modified by any antecedent disease, even those occurring as complications.

In the vast majority of cases cholera runs its course with great rapidity, the greater number of attacks lasting from eighteen to twenty-four hours, the shortest from one to six hours, and the longest from fifteen to twenty days. Its duration is the shortest at the height of an epidemic.

The termination of epidemic cholera may be favorable, the progress of recovery varying widely in different cases; it may be complete in a few hours even, and the patient may return to his ordinary occupation; on the other hand, it may be delayed until after a long and perilous struggle against complications and secondary affections. There may remain a general debility such as is not often seen after any other disease; the emaciated features, languishing expression, capricious appetite, obstinate gastralgia, colic, wakefulness, tendency to coldness, partial or general, and intellectual and moral dejection persist for a long time. An attack has been known to change the whole constitution and temperament of a patient. One attack appears to furnish no immunity against another, and relapses are always to be feared.

Forms.—The forms spoken of—the common or grave, such as has just been described, "cholerine," foudroyant cholera, and paralytic cholera, described by the Russians and Germans—are all merely the same disease, occurring in varying forms of intensity.

Pathological Anatomy.—The alterations of the internal organs in a case of death from cholera bear little relation to the violence of the disease. The appearances are about as follows: Emaciation is general, and there is marked lividity of the lips and nostrils. Rigor mortis is not rare before the warmth of the body has wholly departed. The peritoneal surface is sticky and covered with a viscid exudation; the vessels of the mesentery are engorged with blood. The calibre of the intestinal canal is more often increased than diminished, and always contains some fluid choleraic matter. The fluid is blood-serum, and the thicker material found in it is made up of intestinal epithelial cells and mucus. The intestinal mucous membrane is usually normal in thickness, but is generally denuded of epithelium. The villi are swollen, giving the surface a velvety appearance, and Peyer's patches and the solitary follicles are much enlarged. The glands of the stomach and of the duodenum are enlarged, and the surface is largely denuded of epithelium. There are no special lesions of the other organs. The liver is rarely enlarged, but is usually congested with dark, thick blood. The gall-bladder is also generally distended with bile, which is thicker than normal. The biliary duct is not obstructed. The pancreas presents no marked alteration. The spleen, in rapid cases, is small, hard, and wrinkled upon its surface, of a deep red color on section, and sometimes dotted with ecchymoses; in slow cases it may be slightly enlarged and less deep red in color. The blood is thicker than normal, coagulates slowly, and the separation into clot and serum is very incomplete. The corpuscles are not altered in shape, but there is a remarkable diminution in the proportion of water and neutral salts, and a decrease in the amount of fibrin and albumin. The heart is usually soft and flabby, with ecchymoses in the pericardium. The left side is apt to be empty and contracted, the right distended with dark, thick blood. The arteries are, in general, nearly empty, the veins distended with blood. The pleuræ are very frequently coated with a glutinous, stringy substance, and ecchymoses often appear in the sub-pleural cellular tissue. The lungs are usually healthy, but presenting engorgements at the posterior portions. The bronchi are much congested, and may contain a white, stringy mucus, analogous to that found lining the intestinal canal. The condition of the brain and spinal cord, together with their appendages, is merely that of congestion without special lesion, although it has been declared that there is a sensible increase in their consistency. The ganglionic system presents no change worthy of notice. The muscles are often engorged with blood, and a very marked reddish-brown discoloration of the bones and of the teeth has been noticed in those dying of asphyxia. Renal congestion is the marked symptom in connection with the genito-urinary tract, and the straight tubules are often completely stripped of their epithelium. In those dying in the cold stage the bladder is empty and firmly contracted.

Description of the Spirillum of Cholera and of Certain Organisms Allied to It.—*The Nature of the Contagium Vivum of Cholera* (see Sternberg's "Manual of Bacteriology," New York, 1892.).—Asiatic cholera is without doubt due to a special organism—the so-called "comma bacillus" of Koch—this name being a misnomer, for the bacterium is not a bacillus, but a spirillum.

The parasitic nature of the disease was suspected for a long time. A number of observers had noted the presence, in the cells, of bacteria answering the description of this special one, but it was not until the advance in methods of observation had progressed a long way that it was possible to isolate the organism, and study it under artificial conditions in such a manner as to obtain the evidence necessary to connect it with the process as a causal

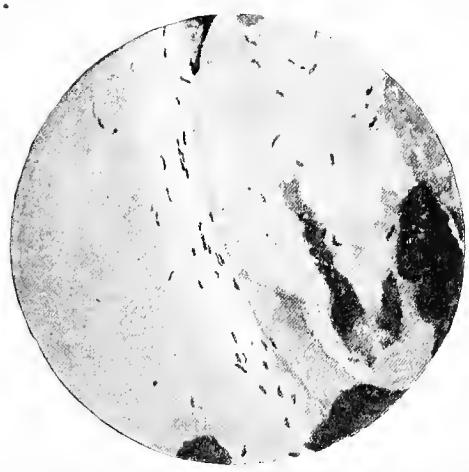

FIG. 17.—Cholera Vibrio. Intestinal Contents of a Man Dead of Cholera. Cover-glass Preparation Stained with Fuchsine. (Fraenkel.) × 1000.

factor. It was in the year 1883 that Koch first discovered and described the spirillum of Asiatic cholera, which he first found during his investigation in Egypt during the epidemic there, and studied further during the following winter in India.

The organism occurs especially in the small intestine, is generally wholly confined to the contents of the intestine and the glandular cul-de-sacs, but is occasionally found in the intestinal walls. It is exceptional to find it in any other part of the body, and it is not strange that investi-

FIG. 18.—Cholera Vibrio. — Bouillon Culture, Two Days Old. Cover-glass Preparation Stained with Fuchsine. (Fraenkel.) × 1000.

gations undertaken with the idea that cholera was a generalized disease were not productive of results. The bacterium is found in large quantities in the dejecta, and sometimes—in fact not infrequently—in almost a pure culture.

In the intestines and in the dejecta it presents the appearance of a short, thick rod, slightly curved in the long diameter, hardly half as long, but considerably thicker than the bacillus of tuberculosis. It usually occurs in this situation singly, but not infrequently it is arranged in pairs, with the curves opposed to each other, and thus recalling the shape of the letter "S". Under cultivation in bouillon it appears longer and thinner, and there are many true spirilla to be seen in the preparations made from such a culture.

A characteristic that is of especial interest, is its

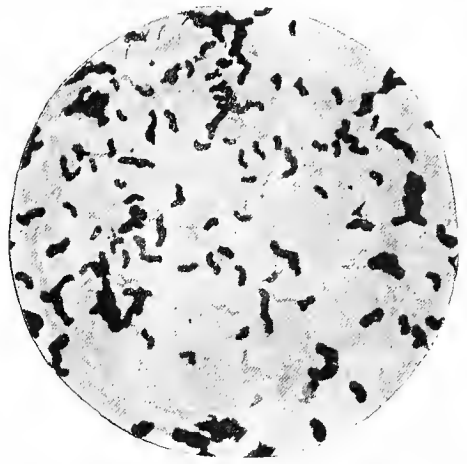

FIG. 19.—Cholera Vibrio. Agar Culture, Twenty Hours Old. Cilia Bearing Cells. Cover-glass Preparation, Stained with Fuchsine. (Fraenkel.) × 1000.

extreme motility, which has been demonstrated by Löffler to be due to a fine cilium placed at one end of the organism.

Shape and motility are not, however, sufficient to differentiate this bacterium from others with similar characteristics—and there are many that possess such,—but the method of development upon the various culture-media is entirely characteristic, and, as shown by Koch, is all that is necessary for separating this one in particular from the others that resemble it. It liquefies gelatine,

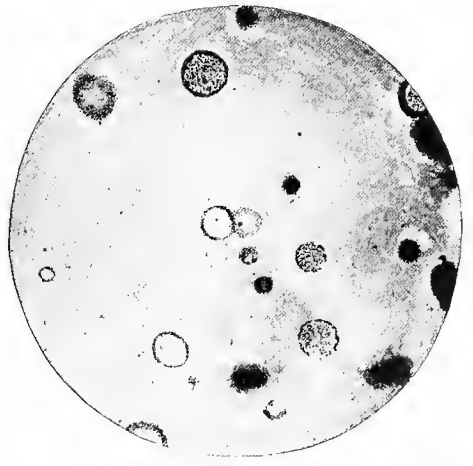

FIG. 20. — Cholera Vibrio. Colonies on Gelatine Plate, Twenty-four Hours Old. (Fraenkel.) × 100.

but it does this slowly, and at the same time a certain part of this liquefied portion evaporates, and as a result there is a special appearance that can hardly be confounded with anything else. At the upper portion of the gelatine, there is a round cavity full of air, and as the surrounding gelatine has remained solid, the appearance is that of a bubble of air in the midst of the upper part of the gelatine and above the liquefied part. The

appearance is wholly different when the organism found by Finkler is put under the same conditions, and equally so with the cheese-spirillum of Deneke.

Description of the Cholera Spirillum.—Discovered by Koch, in 1884, in the excreta of cholera patients, and in the contents of the intestine of recent cadavers. The etiological relation of this organism to Asiatic cholera is now generally admitted by bacteriologists.

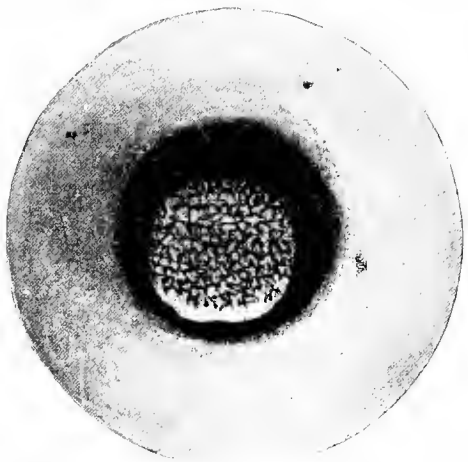

FIG. 21.—Cholera Vibrio. Colony on Gelatine Plate, Forty-eight Hours Old. (Fraenkel.) × 150.

Morphology.—Slightly curved rods, with rounded ends, from 0.8 μ to 2 μ long, and about 0.3 μ to 0.4 μ broad. They are usually but slightly curved, like a comma, but are occasionally in the form of a half-circle, or two united rods curved in opposite directions, forming an S-shaped figure. Under certain circumstances these curved rods may develop into long spiral filaments, and in hanging-drop cultures the S-shaped figures may also be seen to form the commencement of a spiral. In stained preparations the spiral character of the long filaments is often obliterated, or nearly so. When development is very rapid, the short curved rods, or S-shaped spirals, only are seen, but in hanging-drop cultures, or in media in which the development is retarded by an unfavorable temperature, the presence of a little alcohol, and so on, the long spiral filaments are quite numerous, and it is quite generally agreed that the so-called comma bacillus is really only a fragment of a true spirillum.

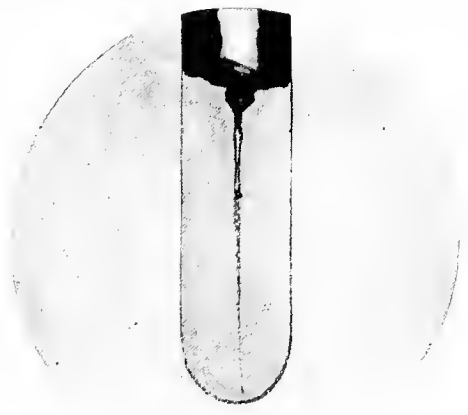

FIG. 22.—Cholera Vibrio. Needle Culture in Gelatine, Forty-eight Hours Old. Natural Size. (Fraenkel.)

By Löffler's method of staining, the rods may be seen to have a single terminal flagellum. In old cultures the bacilli frequently lose their characteristic form, and become variously swollen and distorted. Hueppe has described the appearance of spherical bodies in the course of the spiral filaments which he believes to be reproductive elements, the so-called arthrospores. The cholera bacillus stains with the usual aniline colors, but not as quickly as many other bacteria. It is best stained by a watery solution of fuchsin. It will not stain by Gram's method. Sections may be stained by Löffler's methylene blue.

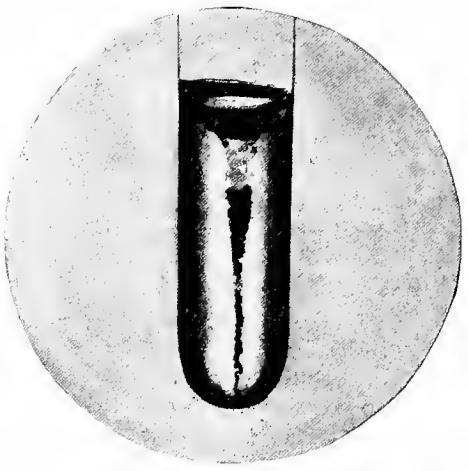

FIG. 23.—Cholera Vibrio. Needle Culture in Gelatine, Six Days Old. Natural Size. (Fraenkel.)

Biological Characters.—It is an aërobic, facultative anaërobic, liquefying, motile spirillum, grows in the usual culture-media at the room temperature, more rapidly in the incubator, does not develop above 42° C. or below 14° C., does not form endogenous spores. It forms arthrospores, according to Hueppe. In gelatine plate cultures, at 22° C., at the end of twenty-four hours small white colonies may be perceived in the depth of the gelatine. These grow toward the surface, and cause liquefaction of the gelatine in the form of a funnel that gradually increases in depth, and at the bottom of which is seen the colony, in the form of a small white mass. As a result of this, the plates on the second or third day appear to be perforated with numerous small holes; later, the gelatine is entirely liquefied. Under a

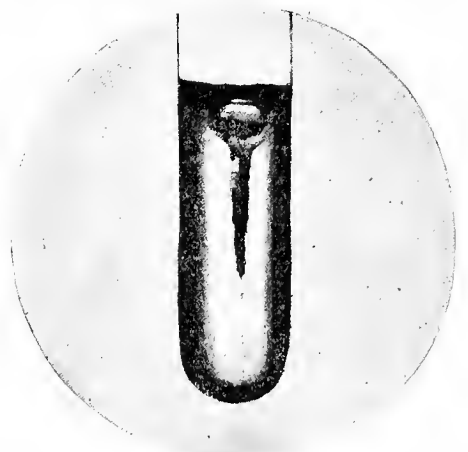

FIG. 24.—Cholera Vibrio. Needle Culture in Gelatine, Three Days Old. Natural Size. (Fraenkel.)

low power, the young colonies, before liquefaction has commenced, present a somewhat characteristic appearance. They are of a white, or pale yellow color, with a more or less irregular outline, the margins being rough and uneven; the texture is closely granular, and the surface looks as if it was covered with little fragments of broken glass, while the colony has a shining appearance. When liquefaction commences, an ill-defined halo is first seen to surround the granular colony, which by transmitted light has a peculiar roseate hue.

In gelatine needle cultures development occurs all along the line of inoculation, but liquefaction of the gelatine occurs at first only near the surface. On the second day, at 20° C., a short funnel is formed that has a comparatively narrow mouth, the upper portion containing air; just below this is the whitish viscid mass. At the end of from four to six days, the funnel, having increased in depth and diameter, may reach the walls of the test-tube. In from eight to fourteen days the upper two-thirds of the gelatine is completely liquefied. Owing to the slight liquefaction occurring along the line of growth the first three or four days, the central mass that has formed along the line of inoculation settles down as a curved or irregularly bent yellowish-white thread, in the lower part of a slender tube filled with liquefied gelatine, the upper part of which widens out, and is continuous with the funnel above.

On the surface of nutrient agar a moist, shining, white layer is formed along the line of inoculation. Blood-serum is slowly liquefied. On potato in the incubator, a rather thin semi-transparent brown, or grayish-brown layer is developed.

In nutrient bouillon, the development is abundant and rapid, especially in the incubator. The fluid is only slightly clouded, but the spirilla accumulate at the surface, forming a wrinkled membranous layer.

Sterilized milk is also a favorable culture-medium.

In general this organism grows in any fluid containing a small quantity of organic material and having a slightly alkaline reaction. An acid reaction of the culture-medium prevents its development as a rule, but it has the power of gradually accommodating itself to the presence of vegetable acids, and grows upon potatoes (in the incubator only) which have a slightly acid reaction. Abundant development occurs in bouillon which has been diluted with eight or ten parts of water, and the experiments of Wolffhügel and Riedel show that it also multiplies to some extent in sterilized river- or well-water, and that it preserves its vitality in such water for several months, but in milk or water containing other bacteria it dies out in a few days. This organism is destroyed, in recent cultures, in nutrient gelatine at 52° C., as determined by Sternberg, the time of exposure being four minutes. A few colonies only develop after exposure to a temperature of 50° C. for ten minutes. In Kitasato's experiments ten or even fifteen minutes' exposure to a temperature of 55° C. was not always successful in destroying the vitality of the spirilla, although in certain cultures exposure to 50 C. for fifteen minutes was successful. The low resisting power to heat, desiccation, and chemical agents, indicates that this organism does not form spores, and many bacteriologists agree that this is the case.

Hueppe has described a mode of spore formation which is different from that occurring among the bacilli, that is, the formation of so-called arthrospores. These are said to be developed in the course of the spiral threads, not as endogenous, refractive spores, but as spherical bodies with a somewhat greater diameter, and somewhat more refractive; but this method of spore formation has not been observed by others who have investigated the question, and cannot be considered as established.

The test for the presence of the cholera spirilla originated by Bujwid and by Dunham consists in the reddish violet color produced in the bouillon cultures containing peptone, or in cultures in nutrient gelatine, when a small quantity (five to ten per cent.) of sulphuric acid is added to the cultures. According to Fraenkel this test serves to distinguish it from the ordinary bacteria of the intestine, and from the Finkel-Prior spirillum, but not from Metschnikoff's spirillum. The reaction is shown by bouillon cultures which have been in the incubator for ten or twelve hours, and by gelatine cultures in which liquefaction has occurred. The sulphuric acid should be quite pure. The color quickly appears, and is reddish violet or purplish red. According to Salkowski, the red color is due to the well-known indol reaction, which in cultures of the cholera spirillum is exceptionally intense and rapid in its development.

The most satisfactory method for obtaining the "cholera-red" reaction,—as we have had lately abundant opportunity to verify,—is that of Beyerinck (Cat. f. Bact. ü. Parasit. Bd. xii. S. 715) in which cultures are made in filtered neutralized one-half per cent. solution of commercial peptone, at 37° C. After twelve to twenty-four hours the cultures are cooled, and from two to five drops of C. P. Sulphuric Acid are added. If the spirillum be present, a very marked and beautiful rose-violet color is produced in the course of a few moments.

A test which is said to distinguish cultures of the cholera spirillum from the spirillum of Deneke and that of Finkler-Prior has been suggested by Cahen. This consists in adding a solution of litmus to the bouillon, and in making the cultures at 37° C. The cholera

Fig. 25.—Cholera Vibrio. Bouillon Culture, Three Weeks Old. Involution Forms. Cover-glass Preparation, Stained with Fuchsine. (Fraenkel.)

cultures show on the following day a decoloration which does not occur at this temperature with the other spirillum named. For determining as promptly as possible whether certain suspected excreta contain the cholera spirilla, a little of the material may be used to inoculate greatly diluted bouillon, gelatine plates being made at the same time. At the end of ten or twelve hours the cholera spirilla, if present, will already have formed a characteristic wrinkled film upon the surface of the bouillon. A little of this should be used to start a new culture in bouillon, and a series of gelatine plates made from it, after which the cholera test may be applied. The result of this, in connection with the morphology of the micro-organisms forming the film, and the character of growth in the gelatine plates, will establish the diagnosis, if the cholera spirillum is present in considerable numbers; if but few are present in the original material it may be necessary to make two or more series of plates and bouillon cultures before a pure culture can be obtained, and a positive diagnosis made.

Pfeiffer has just published (in 1892) his researches upon the cholera poison. He finds that recent aërobic cultures of the cholera spirillum contain a specific toxic substance fatal to guinea-pigs in extremely small doses. This substance stands in close relation with the bacterial cells, and is perhaps an integral part of the same.

The spirilla may be killed by chloroform, thymol, or

by desiccation without apparent injury to the toxic character of this material. It is destroyed, however, by absolute alcohol, by concentrated solutions of neutral salts, and by the boiling temperature, and secondary products are formed which have a similar physiological action, but are from ten to twenty times less potent.

Similar toxic substances were obtained by Pfeiffer

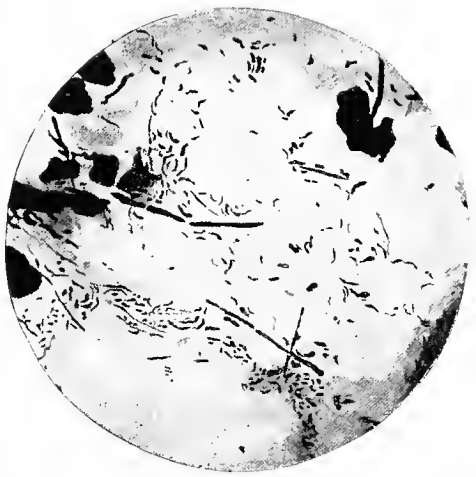

FIG. 26.—Tooth-scraping. Curved Bacilli, Spirochaëte and Leptothrix. Cover-glass Preparation, Stained with Gentian Violet. (Fraenkel.) · 1000.

from cultures of Finkler-Prior's spirilla, and from the spirilla of Metschnikoff.

The spirillum is not found in the blood, nor in the various organs of individuals dead of cholera, but is always found in the discharges during life, and in the contents of the intestines examined immediately after death, frequently in almost a pure culture in the colorless rice-water discharges. It is evident, therefore, that the morbid phenomena must be ascribed to the absorption of toxic substances formed during its growth in the intestine. In cases which terminated fatally after a very

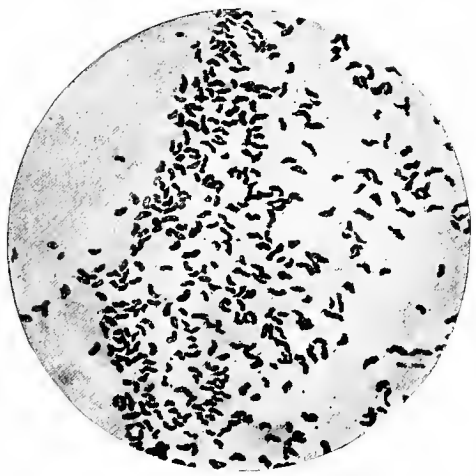

FIG. 27.—Finkler-Prior's Vibrio. Gelatine Culture. Cover-glass Preparation, Stained with Fuchsine. (Fraenkel.) · 1000.

brief sickness Koch found but very slight changes in the mucous membrane of the intestine, which was slightly swollen and reddened; but in more protracted cases, the follicles and Peyer's patches were reddened about their margins, and an invasion of the mucous membrane by the organisms was observed in properly stained sections. They penetrated especially the follicles of Lieberkühn, and in some cases were seen between the epithelium and the basement membrane. As a rule, the spirillum is not present in vomited material, but Koch found it in small numbers in two cases, and Nicati and Rietsch in three. All observers have found the organism always present in cases of true cholera; on the other hand, very numerous control experiments fail to show its presence in the intestinal contents of healthy persons, or in that of those dead from other diseases.

Nicati and Rietsch observed a certain degree of attenuation in the pathogenic power of the spirillum, after it had been cultivated for a considerable time at from 20° to 25° C., and the observation has since been made that cultures which have been kept up from Koch's original material have no longer the original pathogenic power.

Cunningham in his recent publications gives the following conclusions as the result of his own bacteriological studies:

1. In many undoubted cases of cholera he has failed to find the "comma bacilli."
2. In one case he found three different species.
3. From sixteen cases in which he made cultures he obtained ten different kinds of curved bacilli, the characters of which are given in his report.

It is possible that in India, which appears to be the

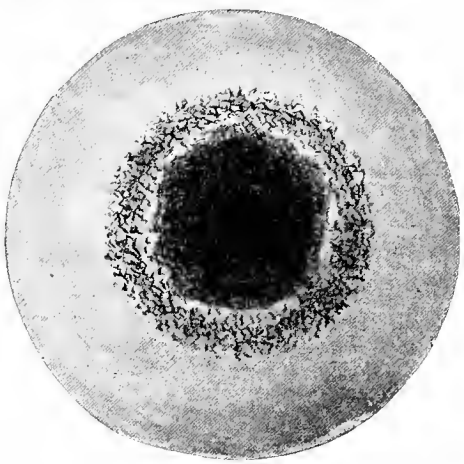

FIG. 28.—Finkler-Prior's Vibrio. Colony on Gelatine Plate, Twenty-four Hours Old. (Fraenkel.) · 100.

permanent habitat of the cholera spirillum, many varieties of this micro-organism may exist, but extended researches made in the laboratories of Europe show that Cunningham is mistaken in supposing that spirilla resembling "comma bacilli" are commonly present in the intestines of healthy persons. Sternberg says that in very extended researches, made in the United States and in Cuba, he has never found any micro-organism resembling Koch's cholera spirillum, in the dejecta of patients with yellow fever, or of healthy individuals, or in the intestinal contents of yellow fever cadavers.

The organism most likely to be confounded with the cholera spirillum, and from which it must be differentiated by the methods of cultivation, as well as by the aid of the microscope, is the spirillum of Finkler-Prior, otherwise called the vibrio proteus. It was obtained by Finkler and Prior in 1884, from the fæces of patients with cholera nostras, after allowing the dejecta to stand for some days. Subsequent researches have not sustained the view that this spirillum is the specific cause of cholera nostras.

Morphology of the spirillum of Finkler-Prior: It resembles the spirillum of Asiatic cholera, but the curved segments are somewhat longer and thicker, and not so uniform in diameter, the central portion being usually thicker than the somewhat pointed ends; it forms spiral filaments which are not as numerous, and are usually

shorter than those formed by the cholera spirillum. In unfavorable media other forms are common, such as large oval, spherical, or spindle-shaped cells. It has a single flagellum at one end of the curved segments, which is from one to one and a half times as long as these. It stains with the usual aniline colors—best with a watery solution of fuchsin.

Biological Characters: Is an aërobic and facultative anaërobic, liquefying, motile spirillum; spore formation not demonstrated; grows in the usual culture-media at the room temperature.

Upon gelatine plates small, white punctiform colonies may develop at the end of twenty-four hours, which under the microscope are seen to be finely granular, and yellowish, or yellowish-brown in color. Liquefaction of the gelatine around these colonies progresses rapidly, and at the end of forty-eight hours is usually complete in plates where they are numerous. Isolated colonies on the second day form saucer-shaped depressions in the gelatine, the size of lentils, having a sharply defined border.

In gelatine needle cultures, liquefaction progresses much more rapidly than in similar cultures of the cholera spirillum, and a funnel of liquefied gelatine is to be seen on the second day, so that by the end of a week the gelatine is usually completely liquefied. Upon the surface of the liquefied medium a whitish film is seen.

Upon agar a moist, slimy layer covering the entire surface is quickly developed.

The growth in blood-serum is rapid and causes liquefaction of the medium.

Upon potato this spirillum grows at the room temperature, and produces a slimy, grayish-yellow glistening layer, which soon extends over the entire surface. The cholera spirillum does not grow upon potato at the room temperature. The cultures give off a fairly strong putrefactive odor, and, according to Buchner, in media containing sugar an acid reaction is produced as a result of their development. They have a greater resistance to desiccation than the cholera spirilla.

Pathogenesis: Pathogenic for guinea-pigs when injected into the stomach by Koch's method, after previous injections of carbonate of soda, but a smaller proportion of the animals die from such injections (Koch). At the autopsy the intestine is pale, and its watery contents, which contain the spirilla in great numbers, have a penetrating, putrefactive odor.

Another organism resembling that of Asiatic cholera is the spirillum of Deneke, called the cheese, or the spirillum tyrogenum, which was obtained by Deneke in 1885 from old cheese.

Morphology of the spirillum of Deneke: Curved rods, and long spiral filaments resembling the spirilla of Asiatic cholera. The diameter of the curved segments is somewhat less than that of the cholera spirillum, and the turns in the spiral filaments are fewer and closer together. The diameter of the segments is uniform throughout, so that this organism more closely resembles the cholera spirillum than does the preceding. It stains with the usual aniline colors—best with a watery solution of fuchsin.

Biological characters: Is an aërobic and facultative anaërobic motile spirillum; spore formation not demonstrated; grows in the usual culture-media at the room temperature, more rapidly than the cholera spirillum, and less so than that of Finkler and Prior. Upon gelatine plates small pin-point colonies are developed, which on the second day are about the size of a pin's head, and have a yellowish color. Under the microscope they are seen to be coarsely granular, of a yellowish-green color in the centre, and paler toward the margins. The outlines of the margins are sharply defined at first, but later, when liquefaction has commenced, the sharp contour is no longer seen. At first, liquefaction of the gelatine causes funnel-shaped cavities resembling those formed by cholera spirilla, but liquefaction is more rapid.

In gelatine needle cultures liquefaction occurs all along the line of puncture, and the spirilla sink to the bottom of the liquefied gelatine in the form of a coiled mass, while a thin yellowish layer forms upon the surface. Complete liquefaction usually occurs in about two weeks.

Upon the surface of agar a thin yellowish layer forms along the needle-track.

Upon potato, at a temperature of 37° C., a thin yellow

Fig. 29.—Finkler-Prior's Vibrio. Needle Culture in Gelatine, Forty-eight Hours Old. Natural Size. (Fraenkel.)

layer is usually developed, but not always, and it contains as a rule beautifully formed spiral filaments.

Pathogenesis: It is pathogenic for guinea-pigs when introduced into the stomach by Koch's method; three out of fifteen animals treated in this way died.

Still another organism resembling the spirillum of Asiatic cholera is: the spirillum of Metschnikoff, obtained by Gameleia in 1888, from the intestinal contents of chickens dying of an infectious disease which prevails in certain parts of Russia during the summer months, and which in some respects resembles chicken

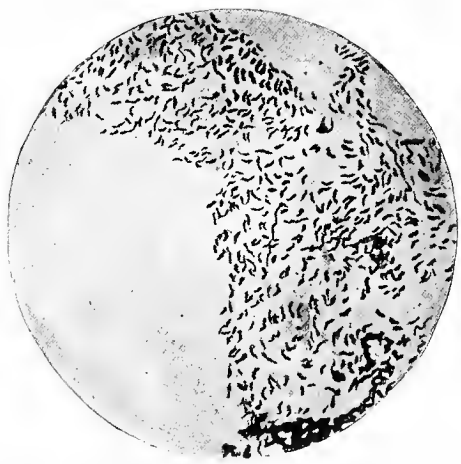

Fig. 30.—Vibrio of Metschnikoff. Gelatine Culture. Cover-glass Preparation, Stained with Fuchsine. (Fraenkel.) × 1000.

cholera. His experiments show that the spirillum under consideration is the cause of the disease referred to, which he calls gastro-enteritis cholerica.

Morphology of the spirillum of Metschnikoff: Curved rods with rounded ends and spiral filaments. The curved segments are usually somewhat shorter, thicker, and more decidedly curved than is the spirillum of Asiatic cholera. The size differs very considerably in the blood of inoculated pigeons, the diameter being sometimes

twice as great as that of the cholera spirillum, and at other times about the same. A single long undulating flagellum may be seen at one extremity of the spiral filaments or curved rods in properly stained preparations. It stains with the usual aniline colors, but not by Gram's method.

Biological characters: An aërobic, facultative anaërobic (?), liquefying motile spirillum. According to Gamaleia, endogenous spores are formed by this spirillum, but Pfeiffer does not confirm the observation, and it must be considered extremely doubtful, in view of the slight resistance to heat (killed in five minutes by a temperature of 50° C.). Grows in the usual culture-media at the room temperature.

Upon gelatine plates small white pin-point colonies are developed at the end of twelve to sixteen hours. These rapidly increase in size, and cause liquefaction of the gelatine, which takes place, however, much more rapidly with some than with others. At the end of three days, large saucer-shaped areas of liquefaction may be seen, resembling those produced by the Finkler-Prior spirillum, the contents of which are turbid, while other colonies have produced small funnel-shaped cavities filled with transparent liquefied gelatine, resembling colonies of the cholera spirilla of the same age. Under the microscope

FIG. 31.—Vibrio of Metschnikoff. Needle Culture in Gelatine, Forty-eight Hours Old. Natural Size. (Fraenkel.)

the larger liquefied areas are seen to contain yellowish-brown granular masses, which are in active movement, with the margins surrounded by a border of radiating filaments.

In gelatine needle cultures the growth resembles that of the cholera spirilla, but the development is more rapid. Upon agar at 37° C. a yellowish layer resembling that formed by the cholera spirilla is quickly developed.

Upon potato no growth occurs at room temperature, but at 37° C. a yellowish-brown or chocolate-colored layer is formed, which closely resembles that produced by the cholera spirillum under the same circumstances. In bouillon at 37° C. development is extremely rapid and the liquid becomes clouded and opaque, having a grayish-white color, while a thin, wrinkled film forms upon the surface. When muriatic or sulphuric acid is added to a culture in peptonized bouillon, a red color is produced, similar to that in cultures of the cholera spirillum, and even more pronounced. In milk at 35° C. rapid development occurs, and the milk is coagulated at the end of a week. The precipitated caseine accumulates at the bottom of the tube in irregular masses, and is not redissolved. The milk acquires a strongly acid reaction, and the spirilla quickly perish.

Pathogenesis: It is pathogenic for chickens, pigeons, and guinea-pigs. Rabbits and mice are refractory, except for very large doses. A few drops of a pure culture inoculated subcutaneously in pigeons, or injected into their muscles, cause their death in eight to twelve hours. At the autopsy an excessive subcutaneous œdema is found in the vicinity of the point of inoculation, and a superficial necrosis may be observed. The blood and the organs generally contain the vibrio in great numbers, showing that the animals die from general infection—acute septicæmia.

In spite of all that has been said since the first announcement by Koch that he considered his spirillum to be the cause of cholera, and the many assertions to the contrary, the relationship between the two to-day is practically universally admitted. The opinion to this effect is based upon a number of reasons, some of which are as follows:

1. The spirillum of Koch has never been found in any other situation, a point that has been established by innumerable observations.

2. This spirillum is found in all cases of Asiatic cholera, without exception, provided that the case is not too far advanced. In such a case there has been a secondary infection, that has killed out the true organism and masked its effects. (To this class must be assigned Emmerich's "Naples bacillus.") Ever since the first announcement of this discovery by Koch, observers have carried out his assertions in all parts of the world where cholera has been investigated at all—in France, Italy, Austria, Hungary, Germany, India, China, Japan, etc.

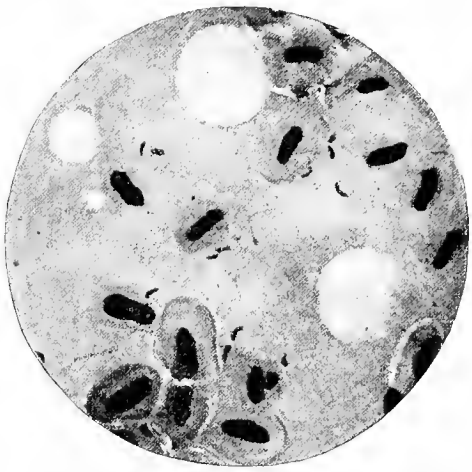

FIG. 32.—Vibrio of Metschnikoff. Pigeon's Blood. Cover-glass Preparation, Stained with Fuchsine. (Fraenkel.) · 1000.

3. This spirillum is found in slight cases as well as in severe. It is present in the beginning of the attack, and it is located in the intestine, that is to say in the region especially attacked by the disease, and in which occur the initial and essential lesions.

The attempts to add to these arguments the more decisive one of successful inoculation experiments, were at the first not satisfactory in their results. Nicati and Rietsch were the first to secure successful results, which they obtained by introducing pure cultures of the organism into the duodenum of guinea-pigs, in which animals they had previously tied the ductus choledochus. By these experiments they obtained symptoms extremely analogous to those of true cholera, and Koch also succeeded in the same direction by passing the infectious material (pure cultures) into the stomach by an œsophageal catheter. In his experiments the animals had been previously narcotized by the injection of tincture of opium, this to prevent peristalsis, and their stomachs had been made alkaline by the introduction of carbonate of soda, a solution to make the stomach alkaline being necessary, because the spirillum of Asiatic cholera will not develop in an acid medium.

Doyen has shown that by introducing alcohol into the stomach the alkaline solution and the tincture of opium may be dispensed with. But, however the experiments may be conducted, they all show one important thing—the great necessity for a healthy condition of the gastro-intestinal tract for the avoidance of infection with cholera. Dyspeptics and alcoholics have been shown in all epidemics to be especially fatally attacked by the disease. It cannot yet be affirmed that the absolute proof of the production of cholera by the specific spirillum has been obtained, because the methods employed in the experiments mentioned above leave too many loop-holes open for the occurrence of accidents, and yet the evidence is so nearly complete that there seems to be no reason for any doubt; the more especially as the exact experimental evidence can probably never be obtained, because none of the lower animals, so far as is known, are susceptible to cholera under natural conditions. The nearest approach to an actual experiment upon man is the case of one of the members of one of the cholera courses held in Berlin in the winter of 1884–85. This man, a physician, was attacked with "cholerine," and after some suffering, but no dangerous symptoms, recovered, the cholera spirillum being isolated from the discharges at various times during his illness. There seems to be no doubt that this was a case of true cholera, arising from some carelessness upon the victim's part in handling the cultures with which he had to deal in the laboratory, for there were no cases of cholera in Berlin at the time, nor had there been for a long time previous.

The entrance of the spirilla is undoubtedly effected by means of the gastro-intestinal tract, and there has not been a particle of evidence from experimental work to favor the theory of Pettenkofer that it ever enters from the air and through the respiratory region.

The acidity of the gastric juice is extremely unfavorable to the growth of the organism, and this explains the liability of the persons with functional or organic disease of the stomach to the attacks of the disease, for in these instances the reaction of the gastric juice is altered or modified so as to allow of the spirillum living until it has passed this point of danger and has reached the intestine, where there are more favorable conditions for its development.

Nicati and Rietsch, and Van Ermengen determined the toxicity of cultures of this organism when they had been deprived of the bacteria, either by filtration or by heating. In 1885, Nicati and Rietsch, by treating similar cultures with alcohol, succeeded in extracting a substance that killed guinea-pigs and rabbits, with the production of cramps and a lowering of temperature. Brieger studied the various chemical bodies that appeared in the cultures of the cholera spirillum; among the number there were convulsivants, methyl-guanidine and a base, $C_3H_8Az_2$, a febricant poison, and compounds that produced inflammation and necrosis. More recently, Brieger and Fraenkel have isolated a toxalbumin, and Petri has determined the presence of a less active substance, toxopeptine.

Hueppe and Scholl have perhaps made as important researches as any in their work upon cultures that have been deprived of free access of oxygen. From such cultures they succeeded in obtaining a peptotoxine that in a dose of 5 c.c., killed guinea-pigs in forty minutes, the animal presenting paralytic symptoms after ten minutes and convulsions after a quarter of an hour. This is a more active poison than was obtained before and was got in larger quantities: an egg after inoculation with a pure culture produced at the end of eighteen days enough to cause the death of ten guinea-pigs. The importance of this is seen when it is remembered that the spirilla are deprived of the access of oxygen when they are developing in the human intestine, and according to these experiments are therefore under the most favorable conditions for the development of this peculiar toxine.

A temperature of from 30° to 40° C. is the most favorable for the development of the cholera spirillum, but it will grow slowly at a temperature as low as 17° C. It ceases to grow at a temperature lower than this, but its vitality is not destroyed, and it grows well when the temperature is again raised; at 10° C. of cold its vitality has been retained, but, on the other hand, a temperature of as low as 56° or 60° C., is sufficient to destroy its vitality in a short time.

Inasmuch as no true spore-formation has been seen to occur in the development of this organism, it is not surprising that drying was shown, first by Koch, to destroy its vitality in a very short time—less than twenty-four hours. But conclusions drawn from his experiments may be misleading, for while this destruction of vitality by drying does occur in a very short time in the case of thin layers, it does not take place under less favorable conditions. This was shown by Kitasato, and by Berkholtz, who saw the vitality retained, the one for thirteen days, and the other for thirty-eight, in experiments in which silk-threads were used for holding the organism during their subjection to desiccation. It should be said, however, that these experiments were conducted in a desiccator, which did not permit the free access of oxygen to the bacteria, and it is undoubtedly the case that this agent is as important as any in the production of the result that it was desired to obtain.

The organism has been found in ordinary drinking-water by Koch in one of the tanks in India, in the neighborhood of which an epidemic of cholera had broken out. It does not live long in distilled water, however, as shown by Meade Bolton, Wolfhügel and Riedel, and others. Strauss and Dubarry found that it lived for fourteen days in one case, and Kraus, for two days only. Other observers have not seen it retain its vitality for anything like so long a time. In ordinary sterilized water it lives longer, according to the experiments of Wolfhügel and Riedel, as well as Pfeiffer, who found that it existed for seven, nine, and twelve months, while Hochstetter lengthened this time to three hundred and ninety-two days. Its vitality appears to be shorter again in non-sterilized water. Strauss and Dubarry found it to be thirty days in one specimen, and thirty-nine in another; while a mixture of other bacteria shortens the time still more. This latter point is one of great importance and has been studied by many experimenters. Koch determined that the organism ceased to live in ordinary drinking-water at the end of six or seven days, and that after twenty-four hours' contact with sewer-water they appeared to be dead; while Schiller, on the other hand, found that they retained their vitality in the same medium for fourteen days. Petri, in an effort to find out how long they lived in the intestine after burial, was able to demonstrate them in cultures at the end of nineteen days. Certain foods may be of great importance in transmitting the organism, as in the case of milk, in which it grows with great energy and without producing the least visible alteration; it has been shown that it will live for at least four days in milk, and forty-eight in butter.

Most of these experiments were conducted with the idea that this organism is an aërobic one, but Hueppe has shown that it is also an anaërobic, and that grown under these conditions the spirillum is possessed of a greater virulence, but it is also easier of destruction. As suggested by Proust, this may explain the comparative rarity of *immediate* infection. The bacterium coming from the intestine as an anaërobic organism is possessed of feeble resisting powers and is therefore easily destroyed, and it is only after it has taken on the conditions of aërobic growth that are furnished it in the medium in which it develops outside of the body that it finds itself possessed of the power of resistance sufficient to enable it to again enter the human body. Such observations are of especial interest in connection with the theory of Pettenkofer (*vide supra*), as seeming to show that his idea of the influence of locality is exact, in so far as this influence is extended in changing the anaërobic to an aërobic organism.

According to Koch, solutions of 1 to 400 of carbolic acid, 1 to 2,500 of sulphate of copper, and 1 to 10,000 of corrosive sublimate are sufficient for the arrest of the de-

velopment of the spirillum of Asiatic cholera. Esmarch and Eisenberg show that creolin will destroy it more quickly than carbolic acid in solutions of the strength of from 1 to 1,000, or 1 to 2,000. Liborius, Kitasato, and Pfuhl have shown the active effect of freshly prepared milk of lime, while Hueppe and Loewenthal seem to have established the important prophylactic and therapeutic value of salol in the management of cholera.

TREATMENT.—*Inoculation Against Cholera.*—Haffkine, whose first article upon the protective inoculation of animals against cholera appeared in the spring (*La Semaine Méd.*, No. 36, 1892), tried the virus upon himself (*Münch. Med. Woch.*, August 9, 1892). He injected subcutaneously in his left side a somewhat larger dose than that used in animals, of the so-called first kind of anti-cholera vaccine, prepared after Pfeiffer's method (Ueber das Choleragift, *Zeit. f. Hyg.*, xi., 393). An illness followed, lasting for twenty-four hours, made up of a rise of 1° C. in temperature, headache, dryness of the mouth, and clouding of the urine, with no disturbance of the digestive tract. There was pain, slight swelling, and glandular enlargement at the seat of the inoculation, the pain lasting five days, and the swelling diminishing gradually until the ninth day. Six days after the first inoculation the other side was inoculated with the strengthened cholera virus (Vaccine No. 2), and there was a second rise of temperature and local pain, but no swelling. The pain disappeared in three days, and the condition became normal in twenty-eight hours, with no digestive disturbances. Similar inoculations were tried in three other persons with like results. In one of these cases a slight diarrhœa which had lasted for several days stopped the day after the injection (first). The inoculation of both kinds of anti-cholera vaccine, the protective power of which in animals has been experimentally proved, is harmless to men, and Haffkine has the hope that six days after inoculation with this vaccine the human organism will have obtained complete immunity against every cholera infection (*Boston Med. and Surg. Journ.*, cxxvii., 227).

Salol in Cholera (*Deut. Med. Woch.*, August 11, 1892). —The treatment first proposed by Loewenthal (first dose of two grammes of salol, followed by hourly or half-hourly doses of one-half to one gramme [Ibid., 1889, Nos. 25 and 26]) has been reported by several authors as producing remarkable results when employed in man. Dr. Gonzales, of Salvador, has used it in fifty-three cases of cholera in one of the Philippine islands with only three deaths (and these were already in the last stages of the disease when they came under observation); the mortality under other methods of treatment being about forty-five per cent.

As a contrast to these results may be quoted those next following, and the paper upon this subject in the *Practitioner* (for November, 1892) will be of interest. It is by Dr. Hehir, of India, who was the first to recommend the use of the drug in India several years ago. After a careful experimentation with it in a large number of cases he concludes that it, like many other drugs, must be considered as having failed to justify the expectations raised in regard to it, and that it should be relegated, like its predecessors, to the limbo of oblivion as far as its special usefulness in cholera is concerned.

The following treatment of cholera was suggested by Nothnagel and Kahler (*Münch. Med. Woch.*, August 16, 1892, and quoted in the *Boston Med. and Surg. Journ.*, September 8, 1892), at the request of the Austrian Government: The use of dilute hydrochloric acid, eight or ten drops to a quarter of a glass of water after meals, the relief of constipation by enemata of boiled water, and the careful treatment of already existing gastric or intestinal catarrh are advised. Colds must be guarded against and attention given to the general hygiene of the body (baths, exercise, sleep). Every diarrhœa must be treated as if it were a choleraic diarrhœa. The patient must be put to bed, if possible after a warm bath, or a hot sitz-bath, with warm compresses on the abdomen, the nourishment limited to barley-broth, and tincture of opium, with tea, rum, or cognac given. If nausea or vomiting appear, carbonated, not alkaline, water is recommended. All drinking-water must be first boiled. Before the patient is put to bed an energetic cold rubbing down is recommended, but this must be superintended by the physician. Calomel comes into consideration only in the very beginning of the disease.

For the treatment of a well-developed cholera attack the tannin enemata recommended by Cantani are best suited, one-half to two litres (quarts) of water boiled, and at a temperature of 39° to 40° C. (102.2° to 104° F.), in which 15 to 20 grammes (3¾ to 5 drachms) of tannin are dissolved, are discharged by high irrigation. This procedure is best suited to the premonitory stage, but can be of use in the fully developed algid stage. The tannin has a limiting action on the development of the cholera spirillum, but is also supposed to counteract and favor the quick elimination of the cholera poison from the blood.

In the stage of asphyxia, in order to counteract the thickness of the blood, hypodermatic injections or intravenous injections may be used to advantage. For the first, two litres (quarts) of distilled water are boiled for half an hour in a vessel, the mouth covered with cotton, 6 grammes (1½ drachm) of carbonate of soda and 8 grammes (2 drachms) of sodium chloride dissolved in it, and cooled to 40° C. (104° F.). This fluid is injected by means of a large, hollow needle, through a fold of skin of the abdominal wall into the cellular tissue. The skin is first to be made thoroughly aseptic.

Instead of a syringe a burette is connected with the needle with a rubber tube. The whole apparatus should be previously disinfected. In the course of a half-hour, 1½ litre (quart) of the fluid can be injected. The skin of the thigh or interscapular region can also be chosen for the injection, and the resulting swelling can be reduced by massage. If after the third injection the relief is only transitory, intravenous injection is to be tried. For this the same solution can be used, or a solution of 5 grammes (1¼ drachm) sodium chloride, with 10 grammes (2½ drachms) sodium sulphate to 1,000 grammes (one quart) of water, previously boiled and thoroughly filtered as the other. In a quarter of an hour, from 2 to 2½ litres (quarts) can be injected into a vein in the arm. The first appearance of the algid stage is the indication for these procedures. For stimulants, champagne, fermented mixtures, heavy wines with the addition of ten to twenty drops of ether, tea with brandy, subcutaneous injections of camphor in olive-oil, in the proportion of 1 to 9, warm baths, energetic and long-continued rubbing with alcohol, or with cloths dipped in ice-water, and warmth to the extremities are useful.

In case of muscular cramps injections of morphine are useful. The treatment of the typhoidal condition, often observed, must depend upon the individual case. It is important to watch for and treat renal complications, and especially to bear in mind the necessity of maintaining the general nutrition.

During the time of cholera, it is well known, according to Sansom (*The Practitioner*, November, 1892), that there are many cases of simple diarrhœa, and the question often comes up as to whether these are to be treated by castor-oil or by opiates and astringents. The author quoted recommends most emphatically the use of castor-oil in moderate doses, offering the following prescription as a good one, viz.: ℞. Ol. ricini, Mucilaginis acaciæ, āā ℥ ss.; Aquæ menth. pip., ℥ ss.; Elixir saecharini, ℥ v. Mix carefully and make an emulsion. In addition to this, and during times of cholera, he recommends also a mixture containing either the sulphite or the sulpho-carbolate of sodium. He thinks he has seen evidence that the sulpho-carbolate acts certainly as an intestinal antiseptic, but if it be employed at all it must be used in much larger doses than are usually given—in children 15 to 20 grains, and in adults half-drachm doses in peppermint-water or cinnamon-water, and repeated every three or four hours. If there be much pain or griping, small doses of compound tincture of camphor (ten-minim doses for children or half-drachm doses for adults) may be added. He thinks that opium in most of its forms does harm. In the acute stages he has never

seen any real good from the use of astringents, but in the later periods, if much looseness continues, astringents, especially in the form of logwood, were useful. He prefers the sodium sulphite to the sodium sulpho-carbolate. These he considers to be the chief principles of medical treatment of cholera until, or unless, the signs of collapse make their appearance. He does not place much reliance upon the statistics in regard to the various methods of treating true cholera, because in the first place cases of simple diarrhœa are likely to be returned as true cholera, and in the second, the variations in the intensity of the disease at various periods of the outbreak must of necessity result in many false deductions. It is an established fact that the mortality of epidemics of cholera is much greater in the beginning of the outbreak, being as much as 60 per cent. and more, and that this very high rate recedes to 25 per cent. or less after the first outbreak.

It appears as if there was a sudden maximum of potential energy in the cholera bacteria that fails as the epidemic goes on, a condition of things that is ascribed by the more recent writers to the development of an acquired immunity among the population, and by others to the change in atmospheric and telluric conditions that become more unfavorable to the development of the organisms. Certain authorities assert that there is no medical treatment that is of avail in the maximum of the epidemic, that a patient in collapse must die, but it is not the part of the practitioner to adopt an attitude of helplessness in such a case.

Upon the approach of collapse it is recommended to place the patient at once either in a hot bath and keep him there, allowing the dejecta to be passed in the tub, or—much more convenient—the hot pack at 100° F. may be usefully employed, reapplications of the hot flannel being made at short intervals. The evacuations are the most difficult to deal with and the most important, because in them lies practically all the danger of the spread of the disease. If they be passed into a bed-pan they should be at once covered with a solution of corrosive sublimate 1 to 1,000, or of carbolic acid 1 to 20, or with a saturated solution of sulphate of iron; and they should be allowed to remain in contact with these solutions for at least six hours before they are allowed to pass into the sewers. But the best method of all is to destroy them by fire, and in this respect the suggestions of Sansom (loc. cit.) are of so much value that we shall quote them entire: "In hospitals receiving cholera patients a special furnace should be provided. In private houses, if possible, a scullery or a room having a fireplace should be appropriated for the purpose and the chimney swept clear. The evacuation should be received upon a large piece of oiled paper (*e.g.*, newspaper), on which layers of tow have been spread. To absorb further the liquid matters, sawdust or peat should be added. On removal from the patient more sawdust or peat should be thrown over the surface, and then a sprinkling of a mixture of powdered nitre and sulphur (proportions of 3 to 1). The whole should be then rolled up in the oiled paper and an outer cover of paper, brushed with carbolized oil, applied. The package is then ready to be taken to the furnace. If no fireplace can be used for the sole purpose, the burning might take place in the open air, care being taken that no nuisance is created. The addition of the nitre and sulphur (to which charcoal or coal-dust may be added if the matters are to be consumed in the open) is not only to promote combustion, but concurrently to disinfect by the sulphurous oxidation products.

"After any attention to the patient whereby it is possible that there may be contact with the evacuated matters, the nurse should plunge her hands into a watery solution of corrosive sublimate, 1 to 1,000, or one of thymol of equal strength, or, preferably, into a solution of thymol in methylated spirit, 1 to 1,000. Experience has abundantly shown that the attendants on cholera patients run scarcely any risks of infection if only contamination by the excreta be avoided."

If there be much pain, inhalations of chloroform may be used, and also, between these, the vapor of nitrite of amyl from the crushed capsules.

If the condition of collapse does not soon show signs of amending, the methods of Cantani, termed by him "enteroclysis" and "hypodermoclysis," may be employed. By enteroclysis is meant a copious enema of hot water, medicated by various drugs, by means of which not only may the irritating contents of the intestine be cleared away, and, perhaps, in some degree disinfected, but fluid may be absorbed from the surface of the intestine to replenish the empty blood-vessels. Long before the epidemic of 1866 Dr. Murray, in India, had recommended the half-hourly injection of a pint of a weak solution of common salt and carbonate of sodium into the rectum at a temperature of 120° F., and is said to have obtained very striking results. Similar means were employed by Sansom (loc. cit., p. 325), in 1866. Cantani advises the addition of tannin to the hot water. From 80 to 320 grains are dissolved in 3 pints or a quart of water or chamomile-infusion at a temperature of 102° to 105° F., and twenty drops of laudanum and an ounce or an ounce and a half of gum acacia are added. Instead of tannin, thymol in solution of hot water (1 to 1,000) has been recommended by other authorities. In the recommendations of the Royal College of Physicians recently (1892), benzoate of sodium, two drachms to a quart of water, has been suggested as an alternative to the tannic acid. In every case the injection should be made with much gentleness. The best position of the patient is that on the back with the hips well raised and the legs well drawn up as for lithotomy. The reservoir douche enema should be used and not the ordinary pump. There is much room for doubt as to whether the addition of any medicament to the hot water is of any special value, the favorable results being due probably to the clearing away of irritant and offensive *débris*, to the absorption of fluid from the intestinal surface, and to the relaxation of the arterial spasm by the hot and moist application. As shown by Cantani, the hot saline solution may pass through the ileo-cæcal valve into the small intestine.

If signs of improvement do not soon follow the procedure described above, recourse should be had to the second method, that specially introduced by Cantani and called by him "hypodermoclysis," and consisting in the injection of a hot saline solution into the subcutaneous tissue. About one drachm of common salt is dissolved in a quart of distilled water at a temperature of 100° to 105° F. The apparatus for this should consist of a glass funnel with a long rubber tube attached to a hypodermic needle of fairly large calibre. The needle is introduced in the gluteal, interscapular, lumbar, or ileo-costal region, the funnel being held at about the level of the patient, and the needle pushed so far in that it may be moved freely in the subcutaneous tissue. The reservoir is then elevated slowly so that the fluid runs into the tissue by the force of gravity and its distribution is aided by the manipulation of the fingers. When about half of the fluid has been introduced the needle is removed and the remainder is injected in another place. The method seems to be rational and is supported by strong evidence by Cantani, who has made extensive use of it. It is easier of application than the older method of intravenous injection that has been employed for many years, and it seems to be attended with better permanent results. Either or both of these methods must be employed earlier than is usually the case, and before the actual symptoms of death have made their appearance; to wait too long is to throw away all chances of success. It must be remembered that even if the dangers of the period of collapse have been safely passed, an ever-watchful care must be exercised, for even after the vaso-motor spasm has passed off there is in some cases the condition of paresis to be reckoned with, and the resulting typhoid state, the tendency to congestions of the viscera, and especially to pneumonia, must be most carefully watched for and guarded against.

General and Special Hygiene.—Measures of precaution in nursing cholera patients (*Brit. Med. Journ.*, September 3, 1892) are thus given by Mr. Ernest Hart, the editor of the journal from which the extract is made. He states that in the epidemic of 1885 the following rules were used and enforced at the London Hospital: The

following disinfectants were employed—the first two or three days Condy's fluid diluted and chloride of lime, subsequently carbolic disinfecting powder and carbolic acid largely diluted (1 to 40), mixed with sawdust in quantities sufficient to wet the sawdust, and sprinkled about the passages, wards, closets, etc.

None of the excreta from the patients were allowed to be emptied into the sewers; instead of this a portion of dilute carbolic acid—about half a pint—was put into each chamber-pail and the conteuts were buried in the garden. The pails had water-tight lids. Burnett's fluid was sprinkled in the cabs that brought the patients. The straw from the beds was burned in each case of death, or where they had been much soiled by excreta. The linen from the cholera wards was washed separately in the laundry of the hospital with McDougall's disinfecting soap. Hot coffee, beef-tea, etc., were recommended to be taken by the nurses at early dawn, and everyone was advised to avoid going on duty on an empty stomach, or in a depressed condition. An extra allowance of wine and of pay was made to the nurses.

Again, although cholera raged so severely in Chili in 1886–87, the doctors and uurses in a number of small hospitals were enabled to protect themselves entirely. Each of the hospitals (Russell) contained from fifty to sixty beds, and had a staff of six doctors, six students, and thirty attendants. All wore long aprons, reaching from the chin to the feet, and caps. For washing the hands and face a solution of corrosive sublimate (1 to 1,000) was exclusively used. In the dining-room all dishes before use were strongly heated by the flame of burning alcohol. The bread was sterilized by toasting. It is stated that no one of the staff sickened who adhered strictly to these precautions. The convalescents before their discharge were bathed in the corrosive-sublimate solution and their clothing was washed in a similar disinfecting solution. The floors of the hospital were made of a kind of pine parquet soaked in tar, and were washed daily with a solution either of copper snlphate or potassic permanganate (1 to 1,000). On emptying a ward it was fumigated, according to rule, by sulphurous acid gas for twenty-four hours.

Instructions of the French Committee on Hygiene as against Cholera, prepared in 1889.—*The germ of cholera is contained in the dejecta and vomited matters of patients. It is transported especially by water, linen, and clothing.*

1. Personal prophylaxis. Follow out a careful hygiene; avoid all causes of fatigue, especially cold, when the body is in a perspiration; excess of all kinds, of wine or of alcoholic liquors, and the excessive use of ice-water; abstain from green fruit. Special attention should be paid to drinking-water; it should be boiled if its origin is suspicious. Natural mineral waters, called table waters, are recommended.

2. Isolation of the sick. The person attacked with cholera should be isolated. The patient should be under constant supervision, and those who have charge of him should be the only ones to have access to him, and these attendants should be governed by the following rules: Take no drink or fluid in the sick chamber, never eat without having washed the hands with soap and a disinfecting solution, bathe the body frequently with a disinfecting solution, and wash the mouth from time to time, and particularly before eating, with a disinfecting solution.

3. The sick chamber. The chamber should be aired many times a day, and curtains, shades, rugs, and all furniture that is not indispensable, removed; the bed should be placed in the middle of the room.

4. Disinfection. The principal disinfectants that are recommended are sulphate of copper, freshly prepared chloride of lime, freshly prepared milk of lime,* corrosive sublimate.

The two following solutions should be used according to the circumstances indicated: First, *the strong*—sulphate of copper or chloride of lime, 5 per cent. solution (that is to say, 50 grammes of the sulphate of copper or the chloride of lime in a litre of water, milk of lime 20 per cent.). The other, *the weak*—sulphate of copper or chloride of lime 2 per cent. (that is, 20 grammes of these substances in a litre of water, milk of lime 7 per cent.). Solutions of corrosive sublimate are to be employed, one to a thousand, *the strong;* or one to two thousand, *the weak*, according to the case. The solutions of sublimate should be colored with fuchsine or eosine, which has been added to a litre of water containing 10 grammes of hydrochloric acid.

Wash the body and hands. For washing the hands use the weak solution.

Rinsing the mouth. For rinsing the mouth use a solution of hydrochloric acid, 4 to 1,000 (that is, 4 grammes of hydrochloric acid to a litre of water).

Dejections. All the dejections of the patient, the vomitus and fecal matters, are immediately disinfected with one of the strong solutions; milk of lime is especially recommended. A tumblerful of one of these solutions should be previously turned into the vessel destined to receive the dejecta. The dejecta are immediately turned into the cabinets, which are also disinfected twice a day with one of the strong solutions.

The cabinets. These are washed twice a day with one of the strong solutions.

Body linen. Soiled body linen is immediately collected, and placed for two hours in one of the strong solutions. It is then sent to the wash, where it is kept for half an hour in boiling water before being cleansed. The unsoiled linen is plunged into one of the weak disinfecting solutions. The same precautions are taken at the laundry. Neither of these classes of linen should be washed in a watercourse, for such water being likely to be drunk later may start a new epidemic.

Clothing. The clothing of the sick and the nurses should be placed for half an hour in a disinfecting oven, in steam under pressure, or in boiling water for half an hour. If these two procedures cannot be carried out, the clothing should be disinfected by sulphurous acid, after the manner indicated below in the disinfection of the infected lodging. Clothing soiled by dejecta should be placed for an hour in one of the strong solutions.

The furniture. Spots or soiled places on the furniture or walls of the room should be immediately washed with one of the strong solutions.

The mattresses and bed furniture. These should be placed in a disinfecting oven, or, when this is not accessible, should be disinfected by sulphurous acid.

Corpses. The corpses should be placed as soon as possible in a tight coffin, that is to say, one with good joints, and well closed and containing a layer of five to six centimetres of charcoal, in order to prevent filtration of fluids, and should be immediately buried.

Disinfection of infected lodgings. A room occupied by a person affected with cholera should not be inhabited until there is complete disinfection.

(*a*) Disinfectiou by sulphurous acid. The procedure is by the combustion of 40 grammes of sulphur to the cubic metre of space to be disinfected, in the following manner: Bands of paper are pasted over the cracks or joints that might let the sulphurous vapors escape. For half an hour water should be boiled in the room in a way to fill it with vapor. Sulphur is broken into very small pieces and placed in pottery vessels, or vessels of cast-iron, with large openings, and holding each about a litre. If of iron, they should be of a single piece, or riveted without solder. To avoid the danger of fire, the vessels containing the sulphur are placed in the centre of basins of iron, holding a layer of five or six centimetres of water. To burn the sulphur, a little alcohol is poured out on it, or it is covered with a little cotton soaked in alcohol, and a match is put to this fluid. The sulphur being lighted, the doors are closed, and paper is pasted over the joints. The room is not opened for twenty-four hours.

(*b*) Disinfection by sublimate. The disinfection of

* In order to obtain very active milk of lime, one should take good quality lime, and slack it little by little with a small portion of its weight of water. When the deliquescence is completed the powder should be placed in a carefully closed receptacle, and a dry situation. As a kilogramme of lime which has absorbed 500 grammes of water for slacking requires a volume of 2,200 c.c., it is enough to add double this volume of water, that is to say, 4,400 c.c., in order to have a milk of lime of about 20 per cent. To disinfect cholera dejecta, it is enough to use a quantity of this milk of lime equal to 2 per cent. of the materials to be disinfected.

plastered walls, or those covered with colored papers, should be methodically carried out over the entire surface of the chamber walls with the aid of a spray of a strong solution of sublimate. The atomizing of this solution should begin at the upper portion of the wall, should follow a horizontal line, and descend successively in such a way that the whole surface will be covered with a fluid layer in very fine drops. All the woodwork should be washed with boiling water, dried, and gone over with the same solution. The municipal administration will inspect the disinfection, and if the inhabitants do not carry it out, will proceed officially. It is part of its duty to see that the inhabitants of a lodging proceed to a serious purification. The room is not reinhabited until at least twenty-four hours have elapsed.

5. *Private Hygiene.* Drinking-water. Great care should be exercised in regard to the purity of the drinking-water. In case of an epidemic drink boiled water. Water coming from sources which possibly are contaminated should be prohibited, and bakers should never, in making bread, utilize such water. The washing of contaminated linen in watercourses is forbidden, as well as throwing into them any material from the dejecta.

Prodromic diarrhœa. It is proper to give special attention to the general condition of the public health, in order to prevent maladies, accidental and only slightly grave in themselves, and notably those of the digestive organs, from producing individual indispositions favorable to the development of cholera. It is therefore necessary to establish preventive medical visits. Physicians appointed for this purpose should exercise a surveillance over the health of the inhabitants of their quarter, and should insist upon the necessity for immediate treatment of intestinal derangement in all cases.

Obligatory information. Every case of cholera, or suspected case of cholera, must be at once declared at the Health Office.

Isolation. The sick person should be immediately isolated.

Inspection. In every house where a case of cholera occurs an immediate inspection is made by a physician delegated by the municipal administration, who should take at once all the necessary measures for isolation and disinfection.

Transportation to the hospital in a special ambulance. When a case of cholera appears in a room containing many inhabitants, the sick person is transported to the hospital in a special ambulance. The chances of cure in such case are greater, and the transmission is not to be feared.

Carriages. The carriages in which persons sick of cholera have been transported must be disinfected. They should be washed with one of the strong solutions.

6. *Public Hygiene.* All causes of unhealthfulness that prepare the region for an invasion of epidemics should be removed when cholera approaches; also, the general rules of hygiene applicable at all times should be more rigorously observed in time of cholera, especially what is concerned with the purity of drinking-water; with crowds of individuals, such as fêtes, fairs, and pilgrimages; with the watching over and feeding of armies; with the proper condition of the soil; with the minute control of closets, and search for possible causes of infection; with the regular removal of filth.

The proper condition of houses, and the particular surveillance over localities, flats, concert-rooms, and all such places meant for the working or industrial population; the condition and regular disinfection of public and private closets; the inspection and disinfection of outhouses; the cleansing of sewers; special inspection of the quarters and houses where cholera prevailed in previous epidemics — all these things are the special duties of the municipal authorities.

The following extracts from the "Report of the Medical Advisory Committee of the Chamber of Commerce of New York, on Certain Points Relating to Quarantine Detention of Passengers and the Disinfection of Passengers' Baggage, Merchandise, and Infected Ships" (Abstract of Sanitary Reports, September 23, 1892, No. 39, Washington) are of great interest, and express the general consensus of medical opinion at the present time. ". . . It should be distinctly understood that in formulating the opinions contained in this report we have limited the scope of our consultation entirely to Asiatic cholera, and to the circumstances of the present epidemic. We report here only the circumstances under which the germs of this disease are liable to enter our country in transatlantic ships, and certain of the measures which seem to us necessary to prevent their access. The control of other infectious diseases offers distinct problems in each case. The opinions which we have formed rest primarily upon this consideration: That under ordinary conditions there is little liability to the introduction of the germs of Asiatic cholera, either through the mails or through ships' cargoes. It is, on the other hand, through the ship's inhabitants and their personal effects that the contagium of this disease is most liable to enter.

"*Merchandise and Mails.*—In view of the facts just stated, we concur in the general conclusion adopted by the International Sanitary Conference at Rome, in 1885, namely, that disinfection of merchandise and of the mails is unnecessary. This general statement, however, must, we believe, be qualified when the merchandise is known to have been prepared for shipment in infected places, has been shipped from infected ports, or has been brought on ships in which cholera has occurred during the voyage. Under either of these conditions it is our opinion that measures of disinfection should be practised. The nature of these measures will depend upon the nature of the cargo, its form of packing, and the circumstances under which it has been placed before or during the voyage. We do not think that general merchandise prepared and packed in uninfected places, in boxes or barrels, or close packages, and which has been shipped at infected ports or brought on infected ships, would need other than such an exterior disinfection as could be practised on the ship or during the unloading without injury to the goods. . . . We believe that merchandise in bales presents greater possibility of contamination from its handling by infected dock-hands, stevedores, or ships' crews at infected ports, or on an infected vessel, than when packed in boxes, and should therefore be subjected to more rigorous inspection and disinfection processes than if it were entirely closed. We are assured by our advisers that hides can be disinfected without injury. A thorough, prolonged, intelligent exposure of rags to live steam or prolonged boiling are the only means known to us by which they may be rendered absolutely safe. . . . We are furthermore of the opinion that, at present, edibles which have either been prepared or packed in infected places should be refused entry altogether. . . .

"*The Inhabitants of Infected Ships and their Effects.*—We have in this report limited the term 'infected ship' to such ships as may have had a case or cases of Asiatic cholera on board during the voyage. . . . We believe that on arrival in port of an infected ship, its passengers should be at once removed to a safe and comfortable place of detention, where they should be isolated in groups as small as practicable and held under observation. We believe that under ordinary conditions the period of quarantine detention of healthy persons when removed, as they should be at once on their arrival in port, from *all known or possible sources of infection*, and properly placed, should be five days, in case no cholera occurs among them. We believe that the baggage of cabin passengers arriving on infected ships should be the subject of most careful investigation as to its point of shipment, its degree of protection from the possibility of contamination while on board, and as to its condition on arrival, and that such manner of disinfection should be practised as may seem necessary to the health officer in view of the facts in each particular case, special attention being paid to the baggage of those who may have taken ship at infected ports, or who have been recently staying in infected towns. We believe that the personal clothing and baggage of the steerage passengers, among whom cholera has occurred during the voyage, should be sub-

jected during their detention to reliable processes of disinfection; and furthermore, that the persons of such steerage passengers should be freed as fully as may be from all possibly infected clothing and effects before they are taken from the infected ships to the place of detention. We hold the opinion that the detention of passengers of any class on infected ships for a moment longer than is absolutely necessary is unjustifiable. . . . We believe that the disinfection of a ship, in which, during a voyage, a case of Asiatic cholera has occurred, cannot be, with certainty, accomplished while its passengers are on board. . . . We have, in this report, not attempted to lay down rules which will govern all cases, nor have we felt called upon to specify particular modes of disinfection. . . . Stephen Smith, M.D., Chairman; A. Jacobi, M.D.; E. G. Janeway, M.D.; T. Mitchell Prudden, M.D.; R. H. Derby, M.D.; Herman Biggs, M.D.; Allan McLane Hamilton, M.D., Secretary."

Harold C. Ernst.

ASPARAGIN. An alkaloid obtained from *asparagus officinalis*. It also may be obtained from marshmallow, lily-of-the-valley, and many other plants. It occurs in hard, brilliant, colorless crystals, with a faintly saline, cooling taste, soluble in water, one part in twelve.

The use of asparagus is being revived, and this alkaloid is recommended as the best means of obtaining its therapeutic properties. It is administered in doses of one to one and a half grain three times a day.

Asparagus has long been known to possess therapeutic properties, but it has not received much attention. The roots and shoots are official in the French Codex, and at many European watering-places it occupies an important position in the articles of diet in lithiasis and in the treatment of gouty patients. It increases the flow of urine and imparts a peculiar strong odor. It may cause vesical irritation, and should be used with caution when the renal tissue is diseased. In cardiac dropsy it is recommended, as its action is said to resemble that of convallaria.

Beaumont Small.

ASTRINGENTS, VEGETABLE, IN CHRONIC INTESTINAL CATARRH. There are three drugs which, in the course of years, I have used, singly or combined, in a considerable number of chronic cases of intestinal catarrh. Each of these drugs contains more or less tannic acid and bitter extracts, but their therapeutic value I have found to be greater than that of tannic acid by itself, and they are apt to disturb the gastric functions either very little or not at all, and can consequently be given for an indefinite period, and without harm.

1. Extractum Monesiæ is derived from the bark of Chrysophyllum glyciphlæum, a Brazilian tree. It was known and used to a great extent some forty or fifty years ago, but has now been almost forgotten. Heydenreich (1839) found it to contain fifty-two per cent. of tannin and thirty-six per cent. of a sweetish substance, probably glycyrrhicin. It is sold in the shape of irregularly shaped, dark brown pieces, is soluble in water, and has a sweetish, astringent, and later rather acrid taste. In doses of five to ten grains it improves the stomachic functions, in larger doses of fifteen grains to half a drachm it is apt to disturb digestion and produce constipation.

2. The well-known Ratanhia root comes from a bush growing in Bolivia and Peru. Wittstein (1854) found in it eighteen per cent. of tannin, some resin, wax, and sugary substances. This extract has a more acrid taste than the former, has similar effects, but is not as well borne by the stomach.

3. The Colombo root derives its name from the African "Kolumb," and belongs to a large species of creeper encountered in the forests of Mozambique and Southeast Africa. Boedeker and Buchner found in it the alkaloids columbin, berberin, and a peculiar acid, some resin and wax, and much starchy substance. For many years the extract and tincture have been in medicinal use as stomachic stimulants, but the natives, and also the Hindoos, use the drug, in the form of infusion or decoction, for diarrhœal and dysenteric diseases.

For a number of years I prescribed extr. monesiæ in the form of a jelly-paste, thus: Extr. monesiæ, ʒ ss.; extr. columb., ʒ ij.; conserv. rosarum, mellis, āā ʒ iij. M. Ft. electuarium. S.: Keep in cool place, and take a teaspoonful three or four times a day. In many cases of otherwise uncomplicated chronic diarrhœa in adults there is often considerable pain and purging, and small doses of morphine or opium may have to be given between the doses of the extract for a week or so, when they may be left off and the remedy continued by itself. Later on, and up to the present time, I have discontinued the use of the paste in all cases that could take pills instead, and I prescribe them as follows: Extr. monesiæ, extr. columb., āā ʒ ss.; extr. gentian. et glycerin., q. s. F. pil. 120; two, three, or four of such pills to be taken three times a day, and to be continued until a cure is established. If it be preferred, the pills may be put up in gelatine capsules. I have the accurate record of at least twelve cases of chronic catarrh of the ileum in adults, and some among them of two or three years' duration, with intervening periods of relative well-being and exacerbation, all of which were cured by the above remedies. At least twenty cases more I have lost sight of, but I may safely say that a cure was effected in every case that was not complicated by organic disease. In children's practice these remedies have not been used by me, but in the form and combination mentioned they have been prescribed for adults alone. Monesia and columbo together act well and produce no dyspeptic symptoms, giving off their tannic acid as they proceed to absorption in the gastro-intestinal tract. And this is a point of importance, that, in the treatment of many chronic functional or simple catarrhal disorders, a positive result may be hoped for, if we are able to continue long enough the use of properly acting remedies, without disturbing by them the functions of the stomach or other organs. I have now used these remedies in so many cases, and have observed their effects for so long a time, that I feel warranted in recommending their more general use.

Leonard Weber.

AUDINAC. A watering-place in the department of Ariége, in the South of France.

Location.—Audinac is situated five miles to the south of Saint-Giron, amid attractive surroundings. Mild climate. Season, June to September. There are two springs yielding an abundance of water having a harsh, styptic taste. Temperature of water, 70° F.

Analysis.—One quart of the water contains:

	Grains.
Sulphate of lime	10.976
Sulphate of magnesia	9.739
Chloride of magnesium	5.391
Carbonate of lime	8.074
Carbonate of iron	1.096
Bitumen	0.972
Total	36.248

Indications.—These purgative and diuretic waters are employed in abdominal plethora, dyspepsia, genito-urinary disorders. They are supposed also to be rather tonic, on account of the iron which they contain.

Accommodation.—Audinac has not kept pace with modern improvements. It is a sleepy French village and no longer a fashionable resort. Still the thermal establishments are not altogether devoid of comforts for invalids, and of the power of the springs there is no doubt.

Edmund C. Wendt.

AUSSEE. A climatic and bathing resort in Steiermark, Austria. (See also Vol. I. of this Handbook.)

Location.—Aussee is charmingly situated among the hills of the so-called "*Salzkammergut.*" It is over 2,000 feet above sea-level. The saline waters are used for brine baths and hydrotherapy in all its forms. The place is also popular with mere tourists on account of its fine

surroundings and the facilities it offers for excursions. Season, July to September.

ACCESS.—Aussee is now a station on the Austrian State Railroad.

INDICATIONS.—The baths are employed with benefit in serofula and neurasthenia. Some phthisical cases and "run-down" people generally do remarkably well there. Diseases of women are largely treated in various private medical establishments, which constitute a special feature at Aussee.

ACCOMMODATION.—Many large and small hotels, sanatoria, institutions, etc. The *Kaiser Franz Joseph's Bad* is a new thermal establishment with excellent arrangements. There are concerts and other amusements, reading-rooms, bowling-alleys, etc. Among the hotels may be mentioned Hackl, Erzherzog Johann, Erzherzog Franz Karl, Sonne, Wilder Mann. Owing to its growing popularity the prices are now relatively high.

Edmund C. Wendt.

AXENFELS. A climatic station on the southern arm of the Lake of Lucerne—that part which is known as the Bay of Uri, about two and one-half miles from the town of Brunnen. The latter place may be reached either by steamboat or by railroad from Lucerne, at the eastern end of the lake, or from Fluelen, at the southern end of the Bay of Uri. From Brunnen Axenfels is reached by the old St. Gothard diligence road, which zigzags up the side of the mountain to an elevation of about two thousand five hundred feet, affording an almost constantly recurring series of magnificent lake and mountain views, such as can be seen in only a few parts of Switzerland.

The hotel (*Hotel et Pension Axenfels*) is a well-built stone structure, with large and airy rooms, all modern conveniences, and pleasant surroundings. While everything is on a more modest scale than at the Hotel Axenstein, which is scarcely a mile distant, in all that relates to the comfort and well-being of its guests, the Axenfels house is in no respect behind its more pretentious neighbor.

Edmund C. Wendt.

AXENSTEIN. A climatic station on the Lake of Lucerne, Switzerland.

LOCATION.—One of the most beautiful spots on the Lake of Lucerne, Axenstein affords a pleasant sojourn to those in need of rest, or "after-cures." It is 2,400 feet above the level of the sea, in a fairly well-sheltered position, and of easy access. The air is "Alpine" in quality. The Axenstein establishment is situated in a picturesque country, near the small village of Morschach. An extensive park surrounds it, planted with pine and fir trees. The excursions are varied and interesting. Two villas situated in the park contain billiard-rooms, baths, etc. There is a telegraph and post-office. English church in one of the villas.

ACCESS.—By the St. Gothard Railroad from Lucerne to Brunnen, thence by omnibus or carriage in one hour to Axenstein.

INDICATIONS.—Milk- and whey-cures are about the only special therapeutic measures made use of here, the place being a popular resort for invalids without serious affections.

ACCOMMODATION.—The *Grand Hotel Axenstein* is a first class Swiss hotel, with all modern comforts, and prices are not yet inconveniently high.

Edmund C. Wendt.

BACILLUS PYOGENES SOLI.[1] I isolated this organism from an abscess which formed at the seat of inoculation in a rat inoculated with an impure smear-culture from an animal dead of tetanus. The smear-culture was one of those made in the manner described for isolating the bacillus of tetanus by Kitasato's method (see this organism under heading Tetanus). It was found impossible to isolate the pyogenic bacillus by plating the pus in the usual way. This was only possible by inoculating from abscesses in animals to culture-media, and from culture-media back to animals a number of times. In this way the contaminating organisms gradually disappeared, and the pus organisms became relatively more and more numerous, until finally all contaminations were got rid of.

The organism resembles in many respects the bacillus of diphtheria. It presents the same irregularities of shape; the swollen, club-shaped extremities; the transverse, unstained, clear spaces in stained preparations; the deeply stained, often perfectly round spots, as are seen in the diphtheria organism. They stain readily with all the ordinary staining solutions, but best with Loeffler's methylene blue. With this stain the older cultures often present a very remarkable appearance, in that there appear bright-red spots in the otherwise blue rods. In some preparations the organisms look as if they had been double stained. The red color is especially evident in the swollen knobs. They have no independent motion, and do not stain by Gram's method.

The growth of the organism is slow on all media. When first obtained it could only be got to grow on gelatine and in beef-tea, but cultures which I have kept reinoculating now for about a year grow equally well on agar. The growth in all cases is scanty. Colonies in gelatine are very small, and appear as round yellowish spots under the lower power of the microscope. Stab-cultures resemble stabs of streptococcus pyogenes; along the bottom of the line of inoculation are discrete, round colonies. Growth on potatoes and on blood-serum is weak, and presents nothing characteristic. In the hydrogen tubes as described for tetanus (see under this heading) the growth is comparatively good.

FIG. 33.—Bacillus Pyogenes Soli (schematic), showing some of the various shapes often met with. × 1,000.

The bacillus is, therefore, a facultative anaërobe, indeed, it seems to grow best where there is paucity of oxygen deep in the stab.

The effects upon animals differ with the mode of inoculation. In rats, gray mice, rabbits, and usually white mice, subcutaneous inoculation of small or large amounts produces an abscess strictly confined to the seat of inoculation. These abscesses form in twenty-four hours, and run a shorter or longer course, depending upon the amount of the culture inoculated. Animals do not suffer from any general symptoms, as a rule, from subcutaneous inoculation, but white mice do sometimes have abscesses in the joints and internal organs. Injections of from one-half to three-fourths cubic centimetre of a liquid culture into the ear-vein of a rabbit produce, in some cases, multiple abscesses in the joints, kidneys, and in other internal organs; sometimes also ulceration of the intestines.

The organism is found aggregated in small and large irregular clumps, seldom separate bacilli, in and among the pus-corpuscles.

Meade Bolton.

[1] Meade Bolton: The Am. Jour. of the Med. Sciences. June, 1892.

BACTERIOLOGICAL TECHNOLOGY. This article is supplementary to that under the title "Micro-organisms" in the REFERENCE HANDBOOK. The same order in the arrangement of subjects has been followed, to facilitate reference, and the principles of bacteriology there expounded are in this article amplified by such selections from the literature of the subject as seem applicable to a work of this nature

STAINING REAGENTS.—Ziehl's Carbolic Fuchsin Solution: Fuchsin (crystals), 1 gm.; carbolic acid, five per cent. aqueous solution, 100 c.c., and add slowly absolute alcohol, 10 c.c. A permanent solution. When used cold this solution stains in a few minutes most forms of bacteria. Wurtz recommends that it should be filtered after forty-eight hours. He advises against its use for staining pathological tissues, as it stains all granular and coagulated matter, and in this way disfigures the preparation.

Kuehne's Carbolic Methyl-blue Solution: Methyl-blue (crystals), 1.5 gm.; absolute alcohol, 10 c.c.; add gradually while mixing, carbolic acid, five per cent. aqueous

solution, 100 c.c. Action is similar to that of Ziehl's solution.

Lithion-Carmine Solution: Carmine, 2.5 gm. to 5 gm.; saturated aqueous solution of lithion carbonate, 100 c.c. Stain for two to three minutes; wash for one-half to one minute in the following: Concentrated hydric nitrate, 1 part; seventy per cent. alcohol, 100 parts. Wash in distilled water, then transfer to alcohol, then to oil, and mount in balsam. Over-staining is impossible, as the color can be removed to any extent by the action of the hydric nitrate alcohol.

Fraenkel's Solution for Decolorizing and Double Staining: Hydric nitrate, 20 c.c.; distilled water, 30 c.c.; ninety per cent. alcohol, 50 c.c.; saturated alcoholic solution of methyl-blue, 66 c.c.

Czenzynski's Solution: Concentrated aqueous solution of methyl-blue, 40 c.c.; one-half per cent. eosine solution (in seventy per cent. alcohol), 20 c.c.; distilled water, 40 c.c. For contrast staining of blood cover-glass preparations.

Fixative for Dry Substances in Making Cover-glass Preparations. v. Sehlen recommends a mixture of equal parts of egg albumen and a cold saturated solution of boric acid. The dry substances are mixed with a drop of this mixture on the cover-glass, and coagulation is effected by passing three times through the flame. It filters clear, and remains unchanged for a considerable time.

Staining of Sections and Cover-Glass Preparations.—Gram's Method, Modifications: Guenther recommends the use of a three per cent. hydric chloride solution in alcohol instead of absolute alcohol, after the section has been removed from the iodine solution; also, the use of xylol, instead of the oil of cloves, for clearing sections.

Weigert suggests washing the section in water or a 0.6 per cent. sodium chloride solution after its removal from the aniline gentian-violet stain, then placing it on a slide and drying it with filter-paper. Gram's iodine solution is applied on the slide and removed with paper. The section is then moistened with aniline oil, which removes the water, and, it is claimed, produces a more marked contrast. The aniline oil is removed and replaced by xylol, and the specimen mounted in balsam.

Fibrine, hyaline matter, etc., are stained a deep blue; micro-organisms are stained a dark violet.

Botkin recommends washing the cover-glass preparation or section in aniline water after its removal from the aniline gentian violet solution and before using the iodine solution. This, he claims, removes the excess of dye from the tissues, and fixes that already taken up by the bacteria.

Staining the Bacillus Tuberculosis.—Ziehl: Cover-glass preparations of sputum or tissue-smears are rapidly and effectively stained by this method. Float the prepared cover-glass on Ziehl's carbolic fuchsin solution in a porcelain capsule, and heat gradually to the boiling-point. After boiling has continued for a few minutes, decolorize without previous washing, in a five per cent. aqueous solution of hydric sulphate, then wash in two to three alcohols (sixty to eighty per cent.) and rinse thoroughly in water. Contrast stain in a watery solution of methyl-blue.

This method is applicable to the staining of the B. tuberculosis in tissues, but the section of tissue should not be heated above 45° C., and must remain in the staining fluid for about one hour.

Ahrens: Dissolve a small crystal of fuchsin in two to three drops of ninety-seven per cent. alcohol (or a few drops of a saturated alcoholic solution may be used) and add to this 2 to 3 c.c. of chloroform. This mixture is at first cloudy, but clears by precipitation, and when clear the prepared cover-glass is floated upon it for four to six minutes. Allow the chloroform adhering to the cover to evaporate, and decolorize with a three per cent. hydric chloride (ninety-seven per cent.) alcohol. Then wash in water and contrast stain with a watery solution of methyl-blue.

In employing this method for tissues the acid alcohol is washed out with absolute alcohol.

Gabbet recommends staining the prepared cover-glass for two minutes, without heating, in Ziehl's solution and washing in water. Then decolorize and contrast stain by immersing the preparation for one minute in the following solution: Methyl-blue (crystals), 2 gm.; twenty-five per cent. hydric sulphate, 100. c.c. Wash thoroughly in water and mount in balsam. This is a simple method and gives good results.

Czaplewski: Stain the preparation in warm Ziehl's solution and after draining off the surplus coloring matter, immerse six to ten times in a solution composed of a saturated alcoholic solution of yellow fluorescin with an excess of methyl-blue and allow the stain to drain off slowly after each immersion. Then contrast stain in a concentrated solution of methyl-blue and wash quickly in water.

The especial advantage claimed for this method of staining is said to be that mineral acids may decolorize many of the tubercle bacilli, while fluorescin does not.

Fraenkel recommends that sections be stained for twenty-four hours in an aniline-water-fuchsin solution, then immersed for one to two minutes in his decolorizing and double staining solution (see above), washed in water, etc.

In cases where the tubercle bacilli are few in number a method of precipitating them in the sputum may be employed.

Biedert: 15 c.c. of sputum are mixed with about 6 c.c. of water, and with from 4 to 8 drops (never more) of a strong solution of sodium hydrate, according to the viscidity. This is then boiled, being continually stirred, and 12 to 18 c.c. more of water are gradually added until a thin fluid is produced.

This is to be stood in a precipitating glass for two days, when the upper layers of fluid are poured off and the sediment stained and examined.

It is well to preserve some of the original sputum, to cause the adherence of the sediment to the cover-glass, as the power of coagulation by heat is frequently lost by the above treatment of the sputum.

Stroschein: 5 to 10 c.c. of sputum are mixed with one to three times their bulk of the following solution: Borax, 1; boracic acid, 3; water to saturation, and thoroughly shaken for one minute. This is allowed to stand for twenty-four to forty-eight hours and the sediment is then examined.

Centrifugal Machine.—This apparatus is employed to precipitate bacteria from urine, milk, and other fluids, with satisfactory results. Its use was first suggested by Litten. (See Fig. 34.)

The apparatus consists of a perpendicular shaft, which supports a metal disk. At the periphery of the disk four test-tube holders are swung, and the disk is made to revolve very rapidly, through the agency of a series of multiplying cogs by turning a crank. One is enabled to accomplish in minutes what formerly required hours, as Professor Litten states.

Staining the Diplococcus Pneumoniæ.—This lancet-shaped bacillus stains easily by the usual methods, but the capsule by which it is encompassed, when found in the tissues, remains unstained.

Staining in Ehrlich's aniline water gentian-violet solution and decolorizing by Gram's method leaves the coccus stained. The capsule is unstained, but remains visible.

v. Kahlden recommends, for demonstrating the capsule, staining for some hours in a one per cent. solution of fuchsin in five per cent. carbolic acid water. This gives a deep red color to the coccus, and the capsule has a pale reddish tint.

Staining the Gonococcus.—In cover-glass preparations made from the suspected secretions, the coccus is easily stained by watery solutions of the aniline dyes, preferably methyl-blue. It is decolorized by Gram's method.

The cocci lie for the most part within the pus-cell, and are mostly grouped about the nucleus. Kratter states that this grouping is more characteristic than the "semmel" shape.

Schutz recommends staining cover-glass preparations for five to ten minutes in a saturated solution of methyl-

blue in five per cent. carbolic acid water. Then immersing for three seconds in dilute hydric acetate, 5 parts; water, 20 parts, and washing thoroughly in water. Contrast stain in a very dilute solution of saffranin.

v. Kahlden recommends staining two to three minutes in an alcoholic solution of eosin and warming. The excess of eosin is absorbed with paper, and the film is then stained for half a minute in an alcoholic solution of methyl-blue. Wash in water, dry, and mount in balsam.

Touton recommends that sections be stained in Ziehl's solution and washed in alcohol.

Staining Actinomyces.—In examining pus for actinomyces the characteristic whitish granules must be sought for. This is best done on a glass plate, upon a dark background. The granules are carefully crushed between two cover-glasses, which are then drawn apart; the film is dried in the air, and the cover passed three times through a flame.

A number of methods of staining have been suggested, but the results are uncertain. For diagnostic purposes double staining in hæmatoxylin and eosin suffices, giving a red color to the fungus and a blue color to the tissue.

Gram's method (staining in Ehrlich's aniline-water

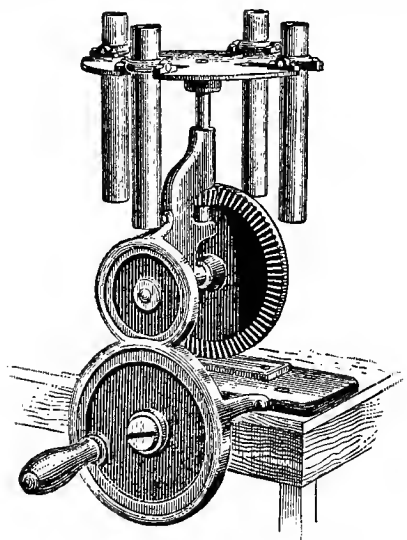

FIG. 34.—Litten Centrifugal Machine.

gentian-violet solution and decolorizing in a solution of iodine—potassium iodide) gives good results when the section is left in the staining solution for twenty-four hours, but is open to the objection that the fungus is liable to fall out when the celloidin is dissolved by the absolute alcohol.

Weigert's stain for bacteria, when preceded by the lithion-carmine stain, produces good results, giving an especially sharp outline to the edge.

Weigert also recommends staining for one hour in Wedl's orseille solution, washing in alcohol, contrast staining in a one per cent. aqueous solution of gentian-violet, again washing in alcohol and mounting in balsam. This gives a blue color to the inner parts of the "ray fungus," and to the outer parts a ruby red.

Israel stains the pear- or flask-shaped ends of the fungus a burgundy-red, by staining for several hours in a solution of orcein in water, rendered acid by hydric acetate.

Staining the Plasmodium Malariæ.—Blood obtained by puncture is quickly spread upon a cover-glass in the thinnest possible film. When dried in the air and passed rapidly three times through a flame the organisms may be stained with an aqueous solution of methyl-blue. The red blood-cells remain unstained.

Plehn recommends, after fixing the film in absolute alcohol, the following solution for double staining: Methyl-blue, concentrated aqueous solution, 60 parts; eosin, one-half per cent. solution in seventy-five per cent. alcohol, 20 parts; distilled water, 20 parts; twenty per cent. potassic hydrate solution, 12 parts. Stain for five to six minutes and wash in water.

Czenzynski's solution may be employed with excellent results for producing a contrast stain. The covers should be floated upon it for some hours at a temperature of 37° C.

Staining of Spores.—Guenther: The cover-glass, being prepared in the usual way, is floated on a solution of aniline-water fuchsin or gentian-violet, in a watch-glass, and very carefully heated to the boiling-point, when it is held entirely away from the flame for one minute. This operation is repeated five times. The cover is then plunged into a three per cent. hydric acetate alcohol, and thoroughly rinsed in water.

The bacilli may be contrast stained by an aqueous solution of the aniline dyes.

Moeller: The cover-glass preparation, dried in the air, is fixed by passing three times through a flame, or by immersing for two minutes in absolute alcohol. It is then placed in chloroform for two minutes, to remove fat-globules and crystals, and washed in water.

Chromic acid has been found so to act upon the spore-covering as to allow the stain to penetrate it. The time required to effect this change in the covering varies from one-half to two minutes. If the action is insufficient the spore does not stain; if too great, the spore is too readily decolorized. To test this action for the species under examination a five per cent. solution of chromic acid is allowed to act upon the specimen for one minute. This effect being noted, a second specimen is treated for a longer or shorter time, as may be required.

After removal from the chromic acid the preparation should be thoroughly rinsed and stained by a few drops of Ziehl's solution being heated upon it for one minute, and brought but once to the boiling-point. Without being washed it is at once immersed in a five per cent. hydric sulphate solution and then thoroughly washed in water.

A contrast stain is produced by immersing the cover for thirty seconds in an aqueous solution of methyl-blue or malachite-green.

Staining of Flagella.—Neuhaus recommends boiling the prepared cover-glass for five minutes upon black logwood ink, "Kaisertinte," and then placing it in a dilute neutral sodium dichromate solution for fifteen minutes. This process must be repeated several times.

Trenkmann stains the flagella of motile bacteria, living in water, as follows: A small drop of fluid which contains the bacteria is spread upon a cover-glass with a large drop of distilled water, and dried in the air. It is then placed, without heating, in an aqueous solution of one per cent. of tannin and one-half per cent. of hydric chloride, for two to twelve hours, and after rinsing thoroughly it is stained from one to four hours in a dilute solution of dahlia or fuchsin (concentrated alcoholic solution, 2 parts; water, 20 parts), gentian-violet, or methyl-violet (1 to 80 parts of water), methyl-blue, etc. Dahlia, fuchsin, and methyl-violet give especially good results.

As this method answers only for staining the flagella of bacteria as found in nature, and not in cultures, he recommends for the latter the following procedure:

Use as culture-medium an infusion of potato, or, if this is not suited for propagating the species of bacterium desired, broth may be employed. In the former case the growth must be diluted five to ten times, in the latter forty to fifty times, before the cover-glass preparations are made. Where it is necessary to make preparations directly from plate cultures, dilute at least one hundred times.

Dry in the air, and, without heating, the covers are placed in the following solution: Tannin, two per cent.; hydric chloride, one-half to one-fourth per cent.; distilled water, q.s., for six to twelve hours or more. After thoroughly rinsing they are placed in Gram's solution, or

in a solution of tincture of iodine, 1 drop; water, 10 c.c., for about an hour, then thoroughly washed and stained for about one-half hour in a very dilute aniline-water gentian-violet solution, as follows: Saturated alcoholic solution of gentian-violet, 1 drop; water, 20 c.c.; aniline water, 80 c.c.

Loeffler at first recommended the use of a corrosive solution before applying the stain, but modified the method by mixing the corrosive material and stain in the same solution, and adding an acid or an alkali as he found necessary.

Add a minute amount of the culture to a small drop of water on a cover-glass and mix carefully so as not to break off the flagella. A small portion of this mixture is transferred to a second, and from the second to a third cover, and dried in the air. The covers are then passed three times through the flame, being held between the thumb and finger to prevent overheating and destruction of the delicate tissue, and are stained by filtering a few drops of the following solution upon the cover-glass: Tannic acid solution (acid, 20; water, 80), 10 c.c.; saturated ferrous sulphate solution, 5 c.c.; methyl-violet, or preferably fuchsin, 1 c.c. This to be carefully warmed until vapor begins to rise. It should never come to a boil.

This solution answers well for staining the flagella of many forms of bacteria, but for certain others it requires to be modified by the addition of an alkali or an acid.

The alkali used is an exact one per cent. solution of sodium hydrate, and the acid a solution of hydric sulphate, of such strength that 1 c.c. will exactly neutralize 1 c.c. of the one per cent. solution of sodium hydrate.

The amount of acid or alkali required to produce the best results in staining the flagella is to be determined by experiment. For the following species it has been shown that to each 16 c.c. of the tannic-acid-iron solution the following additions are necessary: Spir. choleræ Asiaticæ, 1 drop of acid; Spir. rubrum, 9 drops of acid; B. typhosus, 1 c.c. of alkali; B. subtilis, 28 to 30 drops of alkali; B. of Rauschbrand, 29 drops of alkali; B. œdematis maligni, 36 to 37 drops of alkali. The flagella of the B. typhosus are found to be best developed in five to eight hour blood-serum cultures.

Staining Bacteria in Milk or Substances Containing Fat.—Ahrens: Dilute milk with an equal part of water (cream and substances containing a large quantity of fat require greater dilution), and spread in a thin layer on a cover-glass. The film is dried in the air and the cover passed three times through a flame.

Mix 12 to 15 drops of a saturated alcoholic solution of methyl-blue with 3 to 4 c.c. of chloroform, and on this float the cover-glass prepared as directed above, for four to six minutes. On removing from the staining fluid, after allowing the chloroform adhering to the cover to evaporate, wash thoroughly in water and mount in balsam. This makes an exceedingly clear preparation.

Examination of Blood for Bacteria.—For this examination blood must be spread in the thinnest possible layer on the cover-glass and fixed by one of the following methods: 1, By passing three times through a flame; 2, in absolute alcohol; or, 3, and best, by subjecting it for five minutes in an oven to a temperature of 125° C.

Staining such a film for some hours in Czenzynski's solution and washing in water produces exeellent results in contrast staining.

Guentber has suggested washing the film in a one to five per cent. solution of hydric acetate for ten seconds, to remove the normal coloring matter from the red blood-cells, thus making the bacteria more apparent. The hydric acetate is removed first by blowing it off the preparation by means of a tube, and then allowing the fumes of strong ammonia to act upon it for a few seconds. Staining is accomplished by an aqueous solution of the aniline dyes.

Sections of Pure Cultures.—A pure culture, either in agar or in gelatine, after removal from the tube may be hardened for four to eight days, exposed to the light in a one per cent. solution of potassium bichromate, then washed in water and treated with seventy per cent. and ninety-six per cent. alcohols. Gelatine cultures thus hardened are mounted on cork, kept for twenty-four hours in absolute alcohol, and then cut and stained. Agar cultures, after being hardened are to be saturated with bergamot oil, then placed in a soft bergamot oil paraffine, and then in pure paraffine, at 37° C., for twenty-four hours, when sections may be made. Sections should be stained on the slide, cleared only with bergamot oil, and mounted in balsam. Loeffler's alkaline blue and Gram's and Weigert's methods of staining give good results. Colonies from thin gelatine plates may be hardened in the same way, and are then to be treated as sections. To prevent them from folding they should be placed between two slides before immersing in alcohol, and a weight should be placed upon the cover after mounting in balsam.

Culture Methods.—*Sterilization.*—By moist heat. An apparatus known as the Arnold Steam Cooker was first applied as a steam sterilizer by Prudden. It is now manufactured as a steam sterilizer and is largely used in preparing foods for infants, sterilizing surgical instruments and dressings, and is of value for sterilizing clothing and bedding used by persons suffering from contagious diseases, and the clothing of their attendants. It also presents advantages for laboratory use. It consists of (A) a flat, shallow boiler, holding but a small amount of water, and therefore requiring but a minimum amount of heat to produce steam; (B) a reservoir, placed upon the boiler, which it constantly feeds and insures the constant formation of steam; (D) a covered steam-chest or receiving-vessel, placed above the reservoir and connected with the boiler by a cylindrical tube of large diameter (C); and (E) a hood, covering the receiver and enclosing an air-space which is constantly supplied with escape steam. The hood and the steam-jacket which it encloses prevent variations in temperature in the receiving-vessel, so long as the heat applied to the boiler remains unchanged.

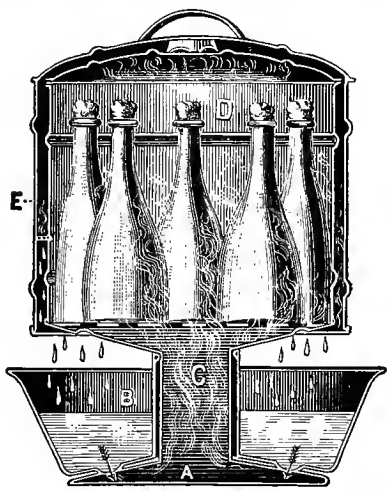

Fig. 35.—Arnold Steam Sterilizer, Sectional View.

By dry heat. A double sheet-iron or tin oven placed on a range or on a gas-stove is employed as an efficient sterilizer.

By desiccation. Koch has shown that the vitality of the spirillum choleræ Asiaticæ is rapidly destroyed by drying, and the same effect is produced upon the vegetative forms of all bacteria, the time required varying with the species. Spores have a much greater resisting power, and some forms are known to retain their vitality for several years. Spores of the B. anthracis, dried on silk threads, after five years have shown active and typical growth and proved to be pathogenic to white mice.

By sunlight. Numerous writers have shown that bacteria are destroyed by the action of direct sunlight upon

them, as well as by the action of diffused light. Vegetative forms are destroyed much more rapidly than are spores. That spores are eventually destroyed seems proven from the experiments of Arloing, Momont, and Gaillard.

The B. tuberculosis, as stated by Koch, is killed in a short time by exposure to the direct rays of the sun, and the same effect is produced by diffused light, when the exposure is continued for several days.

By electricity. Experiments in this line have been made by several writers, those made by Spilker and Gottstein seem to be the most convincing. They used an induction current from a dynamo machine, which was passed through a wire wound around a test-tube containing a culture, the tube being suspended in water. No growth occurred after resowing the culture, and repetitions of the experiment gave similar results.

The strength of the current seems to have a direct effect upon its germicidal power, but in no experiment were the bacteria destroyed in less than one hour.

Pasteurization.—Freeman has experimented in this line and offers an apparatus (now a commercial article) for pasteurizing milk and infant foods. This apparatus consists of a covered tin pail of given size, which is filled to a certain marked level with water which is actually boiling. Into this is placed a second tin vessel filled with water of ordinary temperature and holding the bottles which contain the fluid to be pasteurized. The outer pail is then covered, and the apparatus left standing for one hour, when the bottles are removed and put in a refrigerator to prevent development of any spores which are present.

The apparatus described has been found to raise the temperature of the fluids contained in the bottles to between 73° C. and 76° C., and to hold them at that temperature for a sufficient time to destroy the B. tuberculosis, spir. choleræ Asiaticæ, B. typhosus, etc. Milk treated in this manner shows no visible alteration, and if kept in an ice-box remains unchanged for several days.

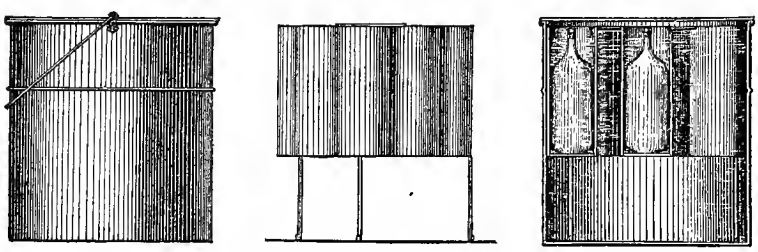

FIG. 36.—Freeman Pasteurizer.

CULTURE - MEDIA.—*Meat Extract Media.*—Liebig's Beef Extract is largely used in preparing nutrient broth, gelatine, and agar. It is substituted in the proportion of one half of one per cent. for the infusion of meat, and makes a most efficient growing medium for most forms of bacteria.

Melting Agar.—To facilitate the melting of agar, it may be soaked over night in water, but the water absorbed must be measured and taken into account.

Soaking agar in a very dilute solution of hydric acetate for some hours facilitates its melting, but this treatment causes it to lose some of its stiffness, which it does not regain.

Neutralization.—For the purposes of neutralization a solution of potassium or sodium hydrate possesses an advantage over the CO_2 salts in not giving off carbon dioxide, which, when held mechanically in the viscid fluid, may mask its proper reaction and cause the medium to be made too alkaline.

A medium, when markedly alkaline, cannot be cleared except by coagulating in it the white of egg. To facilitate this coagulation, which sometimes requires prolonged boiling in an alkaline solution, a single drop of concentrated hydric chloride may be dropped in while the fluid is boiling. This acid does not appreciably alter the reaction.

Schultz recommends the following titration method as a more simple and more exact process for neutralizing media:

Measure out 1 c.c. of the medium to be neutralized, put it in a beaker-glass, standing on white paper, and add one drop of a solution of phenolphtalein (1 to 300 in vinegar) and mix thoroughly. This forms a colorless solution. To this a 0.4 per cent. aqueous solution of sodium hydrate is cautiously added from a graduated pipette until the fluid assumes a pale rose tint. This process is performed three times, the amount of alkali used in each experiment carefully noted, and the arithmetical mean of the three results taken as the amount of alkali necessary to neutralize 1 c.c. of the medium. The figure thus obtained is multiplied by the number of cubic centimetres of medium to be neutralized and divided by ten. The quotient represents the amount of a four per cent. solution of sodium hydrate required to render the whole medium neutral in reaction.

Filtration of broth, gelatine, and agar has been much simplified by employing in the funnel several crossed layers of absorbent cotton, loosely packed, instead of filter-paper. The use of the hot funnel is not required, and the properly neutralized medium can be cleared by passing it several times through the cotton. There is but little likelihood of any of these media becoming too cool to flow during the process, as filtration is very rapid.

v. Freudenreich recommends that agar be filtered through paper in the autoclave. He claims that it is rapidly accomplished, it is thoroughly sterilized, and the medium is crystal clear. He also states that if agar be boiled for two hours at 115° C. and allowed to stand in the unopened autoclave for three hours, it will remain fluid, all the impurities will settle, and a clear medium may be obtained by carefully pouring off the upper layers.

Neisser and Jacobi suggest filtering agar under pressure through 5 ctm. of absorbent cotton, closely packed in a large titrating funnel. They state that filtration by this method requires but a few minutes.

Schultz has suggested the following rapid method of preparing nutrient agar:

To 1,500 c.c. of water, placed in an open enamelled iron vessel, add 18 gm. of agar and boil vigorously over a free flame for thirty minutes. During the boiling 2 gm. of Liebig's meat extract are added, and the thick, white scum which forms is to be removed. The fluid is now cooled to 60° C., and 10 gm. of dry peptone (Witte's) and 5 gm. of sodium chloride are added, together with the entire contents of one or two eggs, which are mixed with sufficient water to replace that which has evaporated.

The reaction, which usually is too alkaline, must be corrected and the mixture is again brought to the boiling point and boiling continued for ten or fifteen minutes.

Filtration is effected through a filter-paper, selected on account of its allowing a rapid filtration, without the use of the hot-water funnel, and may be repeated through the same paper. The process should be completed in an hour, and one litre of medium should be obtained.

The agar thus prepared may be used at once for Esmarch tube-plates, even after the addition of four per cent. of glycerine.

If it is desired to prepare the medium with meat infusion, instead of with Liebig's meat extract, the procedure is modified as follows:

One pound of finely chopped lean meat is digested in 1,500 c.c. of water at 50° C. for thirty minutes, strained through a cloth, boiled for five minutes, and then filtered. To the filtrate, in an agate saucepan, 18 gm. of agar are added, and the process is continued as described above.

Potato.—Esmarch suggests cutting potato in moderately thin slices, placing them in covered glass dishes, measur-

ing not more than 5 ctm. in diameter, and sterilizing in steam for three consecutive days. This answers well for the purposes of culture.

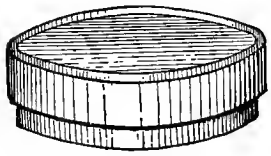

FIG. 37.—Dish for Potato Culture. (Esmarch.)

Roux first suggested placing potato in test-tubes for culture purposes. He cut a core out of the potato with a cork-borer, placed it in a test-tube, the lower end of which had been constricted to form a receptacle for water, and sterilized in steam.

Bolton used larger tubes. The method of preparation is as follows:

A potato squared off at each end, cut out by an apple-corer, and the core thus obtained divided obliquely into two equal parts. Each half is put into a test-tube measuring about 3 ctm. in diameter and 12 ctm. in length, and sterilized for three consecutive days. A small amount of water collects in the bottom of the tube and prevents rapid drying of the medium, while the oblique surface of the potato renders sowing upon it easy, and enables the culture to be readily observed through the tube.

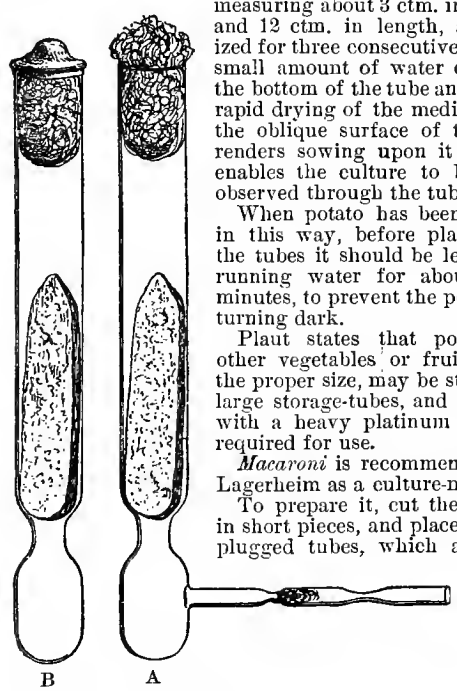

FIG. 38.—Tubes for Potato Cultures. *A*, for anaërobic growth; *B*, for aërobic growth. (Roux.)

When potato has been prepared in this way, before placing it in the tubes it should be left in cold running water for about twenty minutes, to prevent the potato from turning dark.

Plaut states that potatoes, or other vegetables or fruits, cut to the proper size, may be sterilized in large storage-tubes, and fished out with a heavy platinum needle as required for use.

Macaroni is recommended by de Lagerheim as a culture-medium.

To prepare it, cut the macaroni in short pieces, and place in cotton-plugged tubes, which are nearly filled with water. These should be boiled in the steam sterilizer for fifteen minutes, then the excess of water is poured off, and the regular process of sterilization performed.

Many species of bacteria do not grow upon macaroni, but it is useful as an additional medium.

Urine.—Heller has suggested that urine reduced to the specific gravity of 1.010 be used as a culture-medium, to which peptone, salt, gelatine, agar, glycerine, sugar, etc., may be added. He also suggests the use of diabetic and albuminous urine.

Ascitic and hydrocele fluids are used for the purposes of culture, with or without adjuvants. They are to be drawn off from the body by sterilized instruments and received in sterilized vessels. They are prepared as culture-media by the processes employed for blood-serum.

Egg.—The white of egg is an efficient culture-medium.

Schenck recommends using the outer, clear, and most fluid of the albuminous layers, mixed with equal parts of water. This is sterilized discontinuously at 65° to 70° C.

Tarschanoff and Kolessnikoff make a broth-like, a syrupy, and a solid medium from eggs by treating them with potassium hydrate.

They found that eggs in their shells, placed in a ten per cent. solution of potassium hydrate, showed an alteration in the consistence of the albumen. In four days it becomes "fluid-gelatinous-transparent," and in from five to fourteen days it becomes "solid-gelatinous" and faintly yellow, but remains transparent.

The *broth-like* medium is made by using a ten per cent. aqueous solution of the "fluid-gelatinous-transparent" albumen and sterilizing.

The *syrupy* medium is a fifty per cent. aqueous solution of the "fluid-gelatinous-transparent" albumen.

The solid medium may be either α, the "fluid-gelatinous-transparent" albumen placed in tubes and sterilized, or β, the "solid-gelatinous" albumen, cut in thin slices and used unsterilized, in small double dishes.

Blood-serum.—Abbott has suggested an improvement in the method of securing blood-serum. He recommends collecting the blood in museum jars of one gallon capacity, closed by a cover which can be tightly secured upon a rubber joint.

After the blood has stood in these jars for about fifteen minutes, or until clotting has begun, a clean glass rod is passed around the edges of the surface of the clot, to break up adhesions which have formed, and which would prevent the sinking of the clot to the bottom. The covers are then tightly replaced, and with as little agitation as possible the jars are removed to an ice-chest. At the end of about forty-eight hours the firm clot will have sunk to the bottom of the jar, and above it a quantity of dark straw-colored serum is found. This serum should be drawn off with a sterilized pipette and placed in tall cylinders and the blood-corpuscles allowed to settle by standing the cylinders in an ice-chest for twenty-four hours. The clear serum is then pipetted off into tubes or flasks and sterilized by the fractional method.

Kirchner has demonstrated that chloroform added to various fluids will prevent putrefaction in them. He recommends the use of this agent in the strength of one per cent. for preserving storage-flasks of unsterilized blood-serum and milk. Chloroform does not kill spores, but prevents their development, so that when fluids thus preserved are prepared for use the chloroform must be driven off by heat, and sterilization effected by the usual methods.

Blood-serum thus preserved in sealed flasks for more than a year has been successfully used as a culture-medium.

Loeffler mixes three parts of blood-serum with one part of beef-broth containing one per cent. of glucose. This is sterilized and used as a fluid or solid medium. It is recommended for growing the B. diphtheriæ, and Park has shown that within eighteen hours a sufficient growth may be obtained on the coagulated medium to establish a differential diagnosis between diphtheria and the other pseudo-membranous inflammations.

Hueppe combines blood-serum with agar to make plates. He mixes the sterile fluid serum with equal parts of two per cent. nutrient agar to which 0.5 to 1 per cent. of glucose has been added. The following procedure should be closely adhered to, viz., warm the serum to 37° C., melt the agar and cool to 42° to 45° C. and mix them together. The material to be studied is then added and the plate poured before the agar has become solid.

Bumm suggests collecting human blood from the placental end of the cut umbilical cord, in a sterilized vessel. The serum is collected and sterilized in the usual way. From single cases he has secured from 15 to 20 c.c. of clear serum.

Human blood-serum seems to be necessary for procuring cultures of the gonococcus.

PLATE CULTURES.—Petri suggested for plating gelatine and agar, the use of double glass dishes measuring 10 ctm. in diameter and 1.5 ctm. in height. The upper dish is a cover and the lower dish, with its perpendicular edges, serves to hold the medium, and obviates the necessity of using a levelling apparatus and cold stage. The "Petri dish" has in most cases replaced the flat plate formerly used. It seems to be adapted to every need.

"Streak-plates" are made on gelatine and agar, after the medium has been poured in the plates and become solidified, by drawing an infected needle across them in four or five parallel courses. When the number of bacteria on the needle is small, and the streaks are made with a light touch, separate colonies will be found growing along the line which the needle has travelled. This method of plating is especially adapted for use at autopsies.

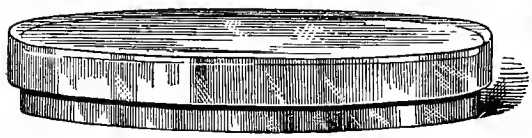

FIG. 39.—Dish for Plating. (Petri.)

ANAËROBIOSIS. — Various methods have been suggested for obtaining bacterial cultures in an atmosphere from which oxygen has been excluded. Some forms, the obligatory anaërobes, require that this condition be absolutely fulfilled, while others, the facultative anaërobes, develop both in the presence and in the absence of oxygen.

The methods described answer the requirements more or less perfectly, but the process is a difficult one to carry out, and attention is required to the minute details.

The oxygen may be removed from the culture by mechanical means, and this is the most usual procedure, or it may be absorbed and enter into chemical combinations which are not broken up by the processes required to obtain a growth of the bacteria in question.

FIG. 40.—Anaërobic Growth Obtained by Deep Puncture.

By means of the air-pump the air may be rarefied, and a large proportion of the oxygen removed, or, as was first suggested by Koch, the medium on a plate is covered with a sheet of mica, beneath which the air is excluded and the growth which occurs remains under observation.

For growth in tubes, Hesse has suggested pouring upon the medium a quantity of sterilized oil.

Librious, after boiling the medium for 20 minutes to drive off the oxygen contained in it, cooled the medium quickly, inoculated the germ to be cultivated, and then sealed the tube.

Roux, after boiling, cooling, and inoculating the medium, poured upon it a thick layer of agar, which, when cool, he inoculated with an aërobic germ, to use up any oxygen which might still be present or which might gain admission.

Deep puncture, with a long platinum needle, in a tube containing a column of nutrient medium, 8 or 10 ctm. in height, is an efficient method of obtaining anaërobic growth. The first growth appears at the lower part of the tube and extends slowly upward, sometimes reaching nearly to the surface of the medium.

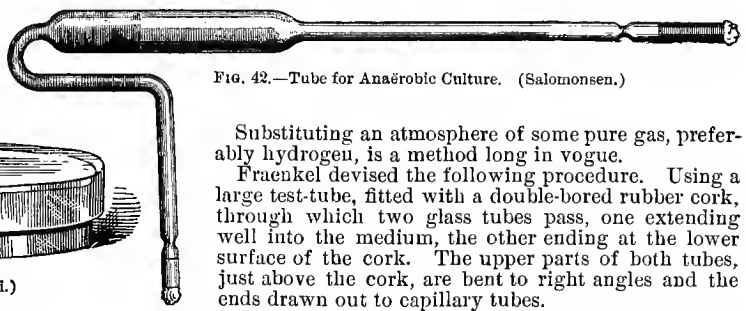

FIG. 42.—Tube for Anaërobic Culture. (Salomonsen.)

Substituting an atmosphere of some pure gas, preferably hydrogen, is a method long in vogue.

Fraenkel devised the following procedure. Using a large test-tube, fitted with a double-bored rubber cork, through which two glass tubes pass, one extending well into the medium, the other ending at the lower surface of the cork. The upper parts of both tubes, just above the cork, are bent to right angles and the ends drawn out to capillary tubes.

Through the longer tube a stream of hydrogen or other gas is passed to replace the air which is driven out through the shorter tube, and when this is accomplished both tubes are sealed, the shorter one first.

After the tubes have been sealed an Esmarch tube-plate may be made.

Salomonsen has devised a culture-tube in which the air may be replaced by hydrogen. It consists of a piece of glass tubing drawn out at both ends, leaving between them a bulb 8 or 10 ctm. in length. One of the ends is bent up upon the bulb, and at the middle of the bulb bent outward at a right angle. After the medium has been introduced, a stream of hydrogen is passed through it from below while it is still fluid. Inoculation is effected by means of a platinum needle, and after the air has been replaced by hydrogen, both ends are sealed.

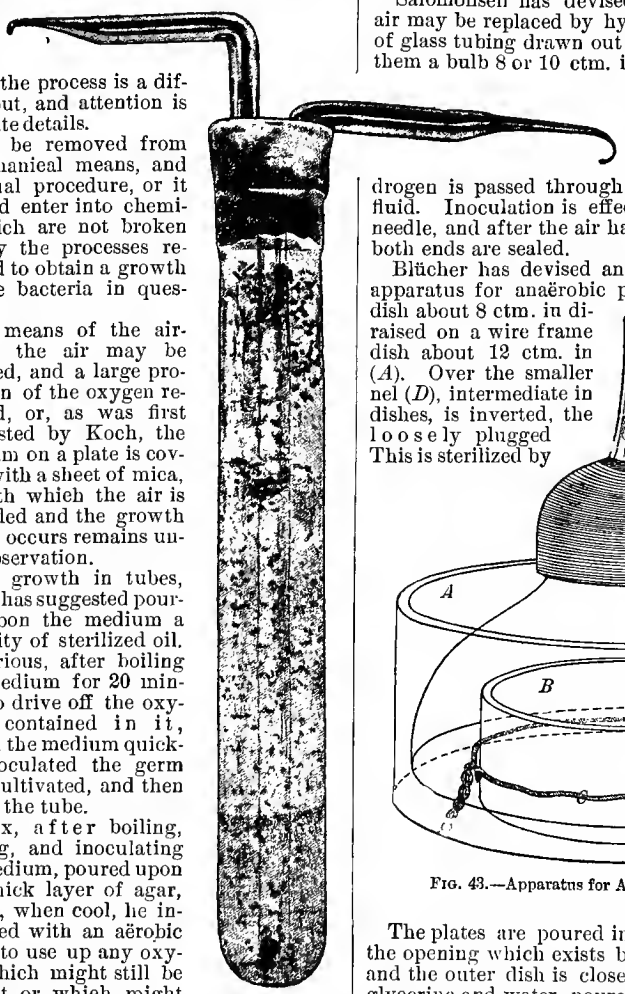

FIG. 41.—Anaërobic Tube-plate. (Fraenkel.)

Blücher has devised an ingenious and very effective apparatus for anaërobic plating. It consists of a glass dish about 8 ctm. in diameter (*B*), which is raised on a wire frame (*C*) and placed within a dish about 12 ctm. in diameter and 5 ctm. high (*A*). Over the smaller dish a tulip-shaped funnel (*D*), intermediate in size between the two dishes, is inverted, the neck of which has been loosely plugged with cotton (*E*). This is sterilized by dry heat.

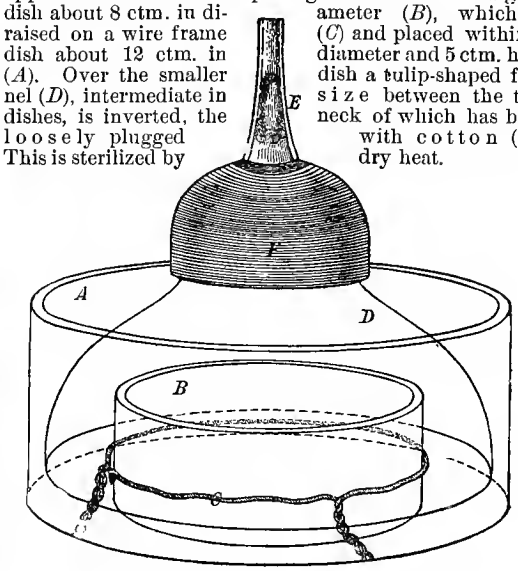

FIG. 43.—Apparatus for Anaërobic Plating. (Blücher.)

The plates are poured into the inner or smaller dish, the opening which exists between the rim of the funnel and the outer dish is closed by a sufficient quantity of glycerine and water, poured into the outer dish, and the neck of the funnel is connected with the gas generator by a piece of rubber tubing, 8 or 10 ctm. in length, which is provided with a spring clip. The gas, passing from

above, drives the air out beneath the rim of the funnel, and when this process is completed, the rubber tubing is closed by the spring clip, the connection with the gas generator is broken and a drop of glycerine placed in the lumen of the rubber tubing, above the spring clip, to effectually seal it. It is necessary to weight the funnel to overcome the buoyancy of the gas contained in it (*F*).

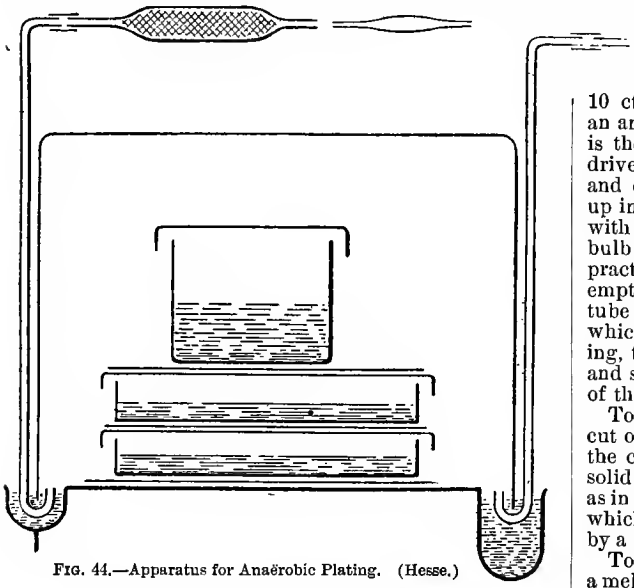

FIG. 44.—Apparatus for Anaërobic Plating. (Hesse.)

Hesse and Botkin have both devised apparatus for growing anaërobic plates.

In both cases a closed chamber is formed by inverting a vessel of considerable cubical contents, within one of slightly greater diameter. A small rack to hold several plates, one above the other, is placed within the chamber, and raised from the floor of the lower vessel.

Hesse seals the opening between the upper and lower vessels with mercury, and conducts the stream of hydrogen through a glass tube curved at its extremity to a short U-shape. The air is conducted off by a similar glass tube placed on the other side, and when the substitution of the hydrogen is completed both tubes are removed without allowing any of the gas to escape.

Botkin uses a liquid paraffine joint, 3 ctm. in height, and conducts both the gas and the air through rubber tubes. These tubes, when bent to the desired shape, retain this shape through the agency of a fine copper wire

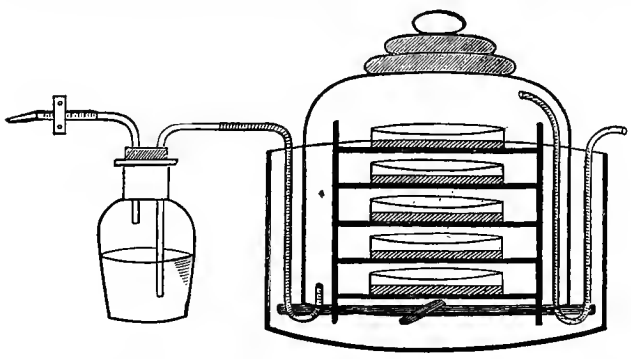

FIG. 45.—Apparatus for Anaërobic Plating. (Botkin.)

previously passed through them. They are easily removed, after steadying the upper vessel, by simply drawing them out.

Esmarch's roll tube-plates may be used for anaërobic growth by filling the tube with gelatine. In doing this it is necessary that the tube-plate already made be held in ice-water, to prevent its melting, while the gelatine, which should be as cool as it is possible to have it, is poured in.

Nikiforoff has devised a bulb for cultures, from which the air can be absolutely excluded. It is made from a moderately thin glass tubing of 1.5 to 2 ctm. diameter, sealed at one end and drawn out to a long capillary tube at the other, leaving a bulb about 5 ctm. in length. The capillary tube is broken at its middle, and at a distance of about 10 ctm. from the bulb it is curved through an angle of 160°. The end of the capillary is then immersed in sterilized water, the air driven out by heating the bulb with a flame, and on cooling some of the water is sucked up into the bulb. To fill such an apparatus with the nutrient medium the water in the bulb must be carefully boiled out, leaving practically a vacuum, and just before the emptying of the bulb the end of the capillary tube is immersed in the desired medium, which must be in a fluid condition. On cooling, the medium flows rapidly into the bulb, and sealing is effected by holding the curve of the capillary tube in a flame.

To allow of inoculation the tube must be cut off where the bulb begins to narrow into the capillary. The process of sowing in a solid medium is the same as in ordinary tubes, after which the tube is sealed by a blow-pipe.

To sow in broth, or in a melted gelatine or agar, he recommends the ingenious method of touching an end of a short, sterilized capillary tube, held in sterilized forceps, to the fluid to be examined. The capillary at once fills, and it is dropped into the bulb, where it falls to the bottom, its contents being washed out by the fluid medium

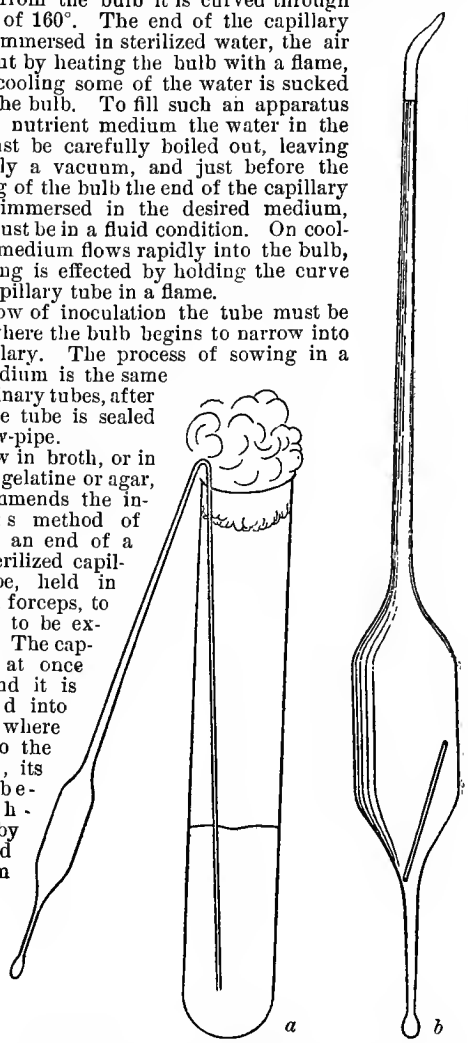

FIG. 46.—Anaërobic Culture-tube. *a*, Method of filling tube with culture medium; *b*, tube inoculated and sealed. (Nikiforoff.)

during its descent. The bulb is then sealed.

Hueppe recommends the use of eggs in their shells for anaërobic cultures.

After external cleansing and disinfection with sublimate, washing in sterilized water, and drying with sterilized absorbent cotton, the egg is thoroughly shaken and a fine opening made at its point, by a sterilized instrument, through the shell and membranes. Through this opening the inoculation is made, and it is afterward covered with sterilized paper and sealed with collodion.

Buchner absorbs the oxygen present in the tubes,

and uses for the purpose an alkaline solution of pyrogallol.

A tube inoculated in the ordinary way is placed in a large test-tube containing 1 gm. of commercial pyrogallic acid. To this 10 c.c. of a 10 per cent. potassium hydrate solution is added from a pipette, and the large tube is quickly closed with a rubber cork and sealed. In twenty-four hours, at 37° C., the contained oxygen is absorbed. At lower temperatures a longer time is required.

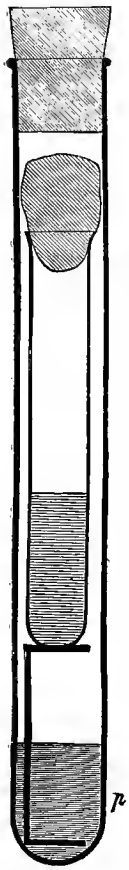

Fig. 47. — Apparatus for Anaërobic Culture. (Buchner.)

It is of advantage to raise the inoculated test-tube above the fluid in the large tube on a glass or metal support (*p*).

Kitasato and Weil have proposed adding to the nutrient medium substances which possess the power of absorbing oxygen. They believed that the good effect of sugar, as used by Liborius, upon the growth of anaërobic bacteria was due to this absorbing power, and they experimented to find a substance which would act more powerfully in this regard.

They found that sodium formate, used in the strength of 0.3 to 0.5 per cent. in nutrient agar, left a clear, transparent medium, and its presence was so beneficial upon the growth of three anaërobic species experimented with, that they recommend its use for this purpose.

They also found very characteristic appearances from growing anaërobes in agar, to which 0.1 per cent. of sodium indigo-sulphate had been added.

Before inoculation and for about twelve hours after it, this medium is bluish-black and opaque. As growth progresses the color changes to one of a greenish tint, the change appearing first in the lower part of the tube and spreading upward. Gradually the growth in the puncture-line becomes apparent, and the agar, which eventually regains transparency, also regains its original yellow or brownish color. In all cases the color of the superficial layers of the medium, to the depth of about two ctm., remains an indigo-blue.

Anaërobic Hanging-drop.—The growth of anaërobic bacteria in hanging-drop has been carried on by apparatus which allowed a stream of hydrogen to replace the air, or from which the air was exhausted by the air-pump. Two much more simple and very efficient methods have been suggested.

Nikiforoff prepares the hanging-drop as usual, upon the hollow slide, and, by slipping the cover to one side, places a small drop of a saturated solution of pyrogallol on the edge of the hollow; then by slipping the cover to the other side he inserts a small drop of ten per cent. potassium hydrate solution, and returns the cover-glass

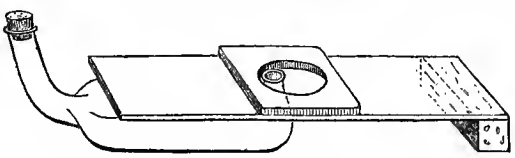

Fig. 48.—Slide for Anaërobic Hanging-drop. (Braatz.)

to its proper place. By careful manipulation the two drops may be run together, and the oxygen is then absorbed. The alkaline pyrogallol forms a dark ring around the hanging-drop.

Braatz also uses the alkaline pyrogallol solution to absorb the oxygen, but forms a retort for it beneath the slide, which is connected through a hole in the slide with its upper surface. Over this opening a glass ring is sealed. The hanging-drop is made in the ordinary way, and sealed with vaseline upon the glass ring. Through another opening in the retort the pyrogallol is first introduced, then the ten per cent. solution of potassium hydrate, and the opening is plugged and sealed.

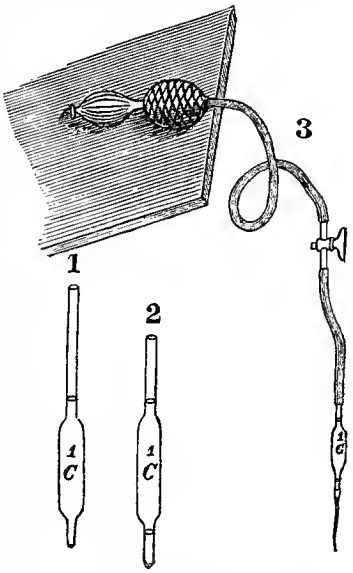

Fig. 49. — Syringe for Animal Inoculation. (Petri.)

Inoculation of Animals. — Petri has recommended an inoculation syringe which seems to present advantages over those formerly used. He employs a graduated glass pipette of 1, 2, or 5 c.c. capacity, with a short tube of exit, which is ground to fit accurately into the shoulder of a hypodermic needle. The needle and pipette are easily sterilized and are the only parts which come in contact with the fluid to be injected.

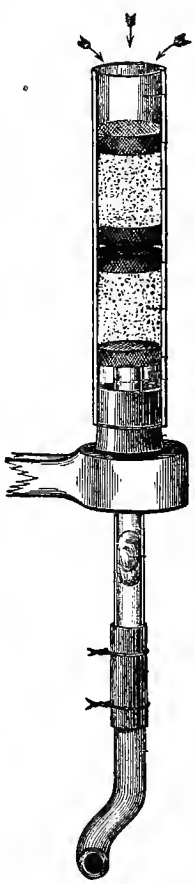

Fig. 50.—Sand Filter for Air Analysis. (Petri.)

The injecting power is supplied by a double bulb, such as is used in an ordinary hand-spray apparatus, and attached to the pipette by rubber tubing, in the course of which a stop-cock has been inserted.

The pipette being filled with the desired fluid, the stop-cock turned to cut off the air, and the bulb being inflated, the needle is introduced into the tissues and by carefully turning the stop-cock enough force can be applied to drive the desired quantity of the inoculating fluid into the body of the animal. Then by turning the stop-cock to cut off the force and withdrawing the needle the operation is completed.

Examination of Air. — It has been demonstrated that the air may be freed from the dust and bacteria which it contains by filtration through various substances and this fact has led observers to employ filtration for studies of air analysis.

After a measured quantity of air has been aspirated through the filter, the bacteria are freed from the filtering substance and grown upon plates. Cotton, glass-wool, and asbestos-wool serve as efficient filters, but the difficulty of spreading these materials in the fluid medium and their opacity have led to a discontinuance of their use.

Petri, after a series of experiments, suggested the use of a column of sand as an air-filter and has devised the following method for its use.

Grains of sand, measuring between 0.25 and 0.5 mm., are collected by means of a series of sieves, and thoroughly burned over a flame for the

purpose of sterilization. This gives them a reddish color.

A glass tube, 9 ctm. in length and 1.5 ctm. calibre, is fitted within its lumen with four disks of fine wire gauze to serve as supports, and between each two of these disks a sand-filter, 3 ctm. in length, is closely packed. Each end of the tube is plugged with cotton and the whole is sterilized in hot air. The filter is now ready for use.

When the apparatus is to be used for an analysis, the cotton plugs are removed and placed in a sterilized covered vessel, and the filter is attached to an exhaust-pump by means of rubber tubing. From 5 to 10 litres of air a minute are drawn through the sand, until the required amount has passed, when the filter is separated from its attachments, the cotton plugs are replaced and the filter preserved for plating.

The method of plating is as follows: After removing the uppermost cotton plug, the upper gauze disk is taken out with sterilized forceps and placed in a sterilized Petri dish. The sand is then poured into the same dish, the melted gelatine added, and the sand spread evenly by short, quick lateral movements of the dish.

The lower sand-filter is then treated in the same manner and the plates preserved for observation.

With the aid of a good hand-magnifier, the colonies of bacteria may be readily distinguished from the grains of sand.

Opaque areas are sometimes formed in these plates, by a grouping of the sand-particles, which may obscure certain parts of the plate. To overcome this objection the use of soluble filters has been proposed. Sedgwick and Tucker have used for this purpose a filter of granulated sugar, about 8 ctm. in length and 3 mm. in diameter, contained in a glass tube. To avoid the risk of contamination in pouring the plates they attached to the tube containing the filter, a cylindrical glass bulb, ruled in squares, into which the sugar used for filtering is to be transferred and in which the plate is rolled. Both ends of the apparatus are plugged with cotton and sterilization is effected at 150° C. in hot air.

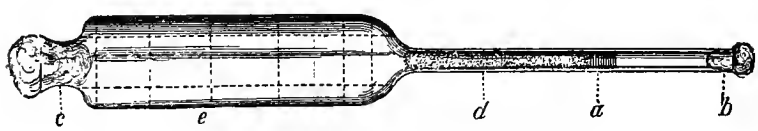

FIG. 51.—Aërobioscope. (Sedgwick and Tucker.)

These writers propose the use of an exhaust receiver of measured capacity provided with a vacuum gauge, to determine the amount of air used. To this receiver their apparatus is attached and the desired amount of air drawn in through it. When this is accomplished the sugar is transferred from the tube to the bulb by careful tapping, a sufficient amount of gelatine is then poured into the bulb, and after the sugar is dissolved a plate is rolled, under a stream of cold running water.

The sand-filter for air analysis may be simplified as follows: In a glass tube, 9 ctm. in length, about 0.3 ctm. in diameter, 6 ctm. of sand, of the size recommended by Petri, are placed, and the column supported on a roll of fine wire gauze pressed into the tube. Both ends of the tube are plugged with cotton and the whole is sterilized in dry heat. After removing the cotton plugs this filter is inserted in a rubber tube connected with an exhaust receiver, as suggested by Sedgwick, and the required amount of air is drawn through it. The plating is effected by scattering the sand used for filtering in a Petri dish and adding the melted gelatine.

The amount of sand used in such a filter is less than that used in the method proposed by Petri, which overcomes an objection to the use of his method, since a satisfactory examination of the plate can be made with a hand-magnifier or with low powers of the microscope.

EXAMINATION OF WATER.—Water for bacteriological examination, taken from the surface of a stream or a faucet, may be collected in a sterilized tube or flask. Samples taken from the deeper parts of a stream are collected in sterilized weighted bottles, fitted with an apparatus to withdraw and replace the stopper, and lowered to the desired depth.

Water should be plated as soon as possible after it has been obtained. Should it be necessary to transport it before the plates can be made, the bottle containing it should be packed in ice.

The quantity of water used for an analysis must depend upon the number of bacteria which it contains. One cubic centimetre is the amount usually employed, but less should be used if more than five hundred colonies develop from this amount. For quantitative analysis a measured quantity must always be employed, a drop, being an indefinite quantity, is not to be recommended.

The colonies should be counted on the third or fourth day. *T. M. Cheesman.*

BAD BRONN. An Alsatian watering-place, known also as Kestenholz (Ger.) and Châtenois (Fr.).

LOCATION.—Kestenholz is prettily situated not far from Strasbourg, and within sight of Schlettstadt on the river Rhine. It is an unpretentious, quiet resort, with four saline and moderately alkaline springs, flowing in great abundance, and having a temperature of about 64°F. It is chiefly frequented by ladies. Although the water contains traces of sulphuretted hydrogen, it is not unpleasant to the taste. The baths are refreshing, and the thermal establishment is modern in its appliances. There are beautiful natural promenades through chestnut-plantations and fine forests. The walks resemble those of Marienbad. Mr. Wolff writes as follows concerning this place ("The Watering Places of the Vosges, 1891"): "Apart from the use of the waters, for a cheap sojourn in foreign mountain country it would not be easy to hit upon a fitter place than Châtenois. It is easily reached, being situated on the branch-line from Schlettstadt to Markirch, at the junction of the valleys of the Leber (Lièpvre) and of Weiler (Val de Villé), both exceedingly pretty and at the same time interesting valleys, leading up to the lofty ridge which rises farther south to the high points of the Schlucht and the Hohneck."

ANALYSIS.—In 1,000 parts there are contained:

Free carbonic acid	traces
Sulphuretted hydrogen	traces
Chloride of sodium	3.200
Chloride of magnesium	0.078
Chloride of potassium	0.010
Sulphate of soda (anhydrous)	0.086
Sulphate of magnesia	0.050
Sulphate of lime	0.020
Silicate of soda / Bicarbonate of soda	0.050
Silicate of lime	0.410
Silicate of magnesia	0.270
Silicate of iron and of manganese	0.020
Basic salts of bromine and of iodine	strong traces
Organic matter, in combination with lithia silicic acid and ammonia	0.020
Fluorine, arsenic, lithia	strong traces
	4.214

INDICATIONS.—These saline waters are useful in rheumatic and gouty affections, hepatic plethora, catarrhal affections of the bowels, anæmia and chlorosis. For conditions of neurasthenia the place itself, apart from the springs, has undeniable advantages. Tuberculosis and cutaneous affections are also said to be much benefited by a course of these waters, but this statement must be taken *cum grano salis.*

ACCOMMODATION.—A new hotel is in course of construction, the older ones are mediocre, though clean. The usual sprays, douches, pine-needle baths, inhalations, etc., are provided. But everything is on a small scale. It is a cheap place—Mr. Wolff stating that one dollar a day will about cover all necessary expenditures. *Edmund C. Wendt.*

BADEN-BEI-ZÜRICH, so called to distinguish it from the other European Badens, is a popular watering-place of Switzerland, only a short distance from Zürich.

LOCATION.—This Baden was at one time the most fashionable spa of Europe. It is prettily situated in one of the most picturesque spots of the Jura Mountains. The river Limmat pierces the mountain chain here on its way down from Zürich. There are beautiful promenades with fine views of the Alps. Richly wooded hills are found in all directions. The elevation of Baden above sea-level is less than twelve hundred feet. There are a number of sulphurous springs, rich in chloride of sodium, and having a temperature of 118° F. They furnish about one million litres a day. It is a quiet place now.

The climate is bracing, and the temperature on the whole equable. It is an all-the-year-round resort, but is largely frequented only during the warmer months.

ACCESS.—Baden is a station on the railroad from Zürich to Bâle, thirty minutes from Zürich.

ANALYSIS.—One quart of Baden mineral water contains:

	Grains.
Sulphate of soda	2.218
Sulphate of magnesia	2.442
Sulphate of lime	10.860
Chloride of potassium	0.711
Chloride of sodium	13.042
Chloride of magnesium	0.566
Carbonate of lime	2.599
Carbonate of magnesium	0.152
Carbonate of strontium	0.005
Fluoride of calcium	0.016
Chloride of calcium	0.719
All other ingredients	0.013
Total of solids	33.343

INDICATIONS.—Baden was known to the Romans, and has a good reputation in the treatment of gouty and rheumatic affections, motor disturbances after fractures and dislocations, metallic intoxications, and all digestive and respiratory troubles on a lithæmic basis. It is also a "*Terrain-Kurort*" for the Oertel method of treating cardiac affections and obesity.

The baths have all modern appliances and comforts.

There are opportunities for milk-, whey-, and grape-cures. Inhalation-rooms, massage, etc., are not wanting to meet the requirements of certain cases.

ACCOMMODATION.—There are numerous "bath-hotels," such as the Bären, Blume, Limmathof, Hirsch, Schwan, etc. There is a fairly good *Kurhaus*, with salons, reading-room, etc. An orchestra plays from April to October, and there are two theatres. The proximity to the University town of Zürich is an advantage. Not many English and American visitors go there now.

Edmund C. Wendt.

BADENWEILER. A popular watering-place and climatic station in the Black Forest, known to the Romans as *Aquæ Villarum*.

LOCATION.—Badenweiler is pleasantly situated in the southern part of the Black Forest, in the Duchy of Baden, near the university town of Freiburg. It has only about six hundred inhabitants, but is annually visited by over five thousand patients and tourists. It is one thousand three hundred feet above the sea-level, and the pure air, impregnated with the balsamic odors of the surrounding pine woods, is a factor which adds greatly to the popularity of the place as a health-resort.

Dr. C. W. Allen, of New York, recently spent some time there, and has given his impressions in the *St. Louis Courier of Medicine*. There are interesting remains of the old Roman baths, still showing the usual *atrium*, *vestibulum*, *frigidarium*, *calidarium*, *tepidarium*, etc. The new baths are equipped with all the modern appliances of a complete establishment, such as douches, showers, sprays, inhalation-cabinets, etc. The waters of the springs are earthy and slightly alkaline, having a temperature of 80° F. and flowing at the rate of 1,140 litres per minute. It is a peculiarly pleasant water to swim and bathe in, according to Dr. Allen's personal experiences.

The higher peaks of the Black Forest shut in the little village from the northeast and partly from the south, while it is open toward the Vosges Mountains on the west. Sharp and raw winds are unknown, the ground dries quickly after rains, and even in the woods no unpleasant dampness is felt. The temperature is even, the night and day variations being slight. The place is very healthy, the mortality (exclusive of the first year of life) being only about fourteen per thousand. There are excellent facilities for many highly picturesque excursions. From near-by mountains fine views of the Alps, Jura, Vosges, and the Valley of the Rhine are obtained. Season, May to October.

ACCESS.—From the station Mühlheim, on the railroad, between Bâle and Freiburg, by omnibus or carriage.

INDICATIONS.—Diseases of the chest, nervous and catarrhal affections, neuralgia, rheumatism, female diseases, neurasthenia, anæmia, protracted convalescence, are all treated with happy results at Badenweiler. There are plenty of amusements—concerts, theatre, "Italian nights," etc. Cows', goats', and donkeys' milk. A special feature is made of the grape and whey cure. Badenweiler is also a so-called "*Terrain-Kurort*" (Oertel) for cases of heart disease.

ACCOMMODATION.—There are good hotels, chief among which are the Hotel Sommer, Römerbad, and Sonne. Apartments in villas are also found, and there are quite a number of good boarding-houses. The *Kurhaus* is elegantly fitted up with a ball-room, reading-rooms, etc. It is a commodious structure and under good management. There is a moderate "cure-tax" for visitors and patients.

Edmund C. Wendt.

BAD HEILBRUNN. A popular watering-place in Bavaria, Germany.

LOCATION.—Heilbrunn (healing spring) is prettily situated near the Bavarian Alps. It is two thousand five hundred feet above sea-level. Attractive scenery and abundant vegetation add to the charm of the little village.

ACCESS.—By way of Munich to station Tölz, thence by omnibus.

ANALYSIS.—The waters of the spring called Adelhaid's quelle are rather rich in bromides and iodides. In 1,000 parts of water there are contained:

Sodium chloride	4.758
Sodium carbonate	0.777
Calcium carbonate	0.073
Magnesium carbonate	0.018
Sodium iodide	0.027
Sodium bromide	0.046

The spring has a temperature of 50° F. The water is limpid and sparkling, and something like 60,000 bottles are exported annually.

INDICATIONS.—Cutaneous and syphilitic affections, scrofula, also anæmia and catarrhal affections of the air-passages, are chiefly treated at this place. But obesity, goître, and diseases of women are said to do well there also.

ACCOMMODATION.—Rather primitive and not over clean. There is a *Badehaus* and a number of boarding-houses. Summer season only.

Edmund C. Wendt.

BAGNOLLES.—A watering-place in the Department of Orne, France.

LOCATION.—Bagnolles (not to be confounded with Bagnols-les-Bains), is situated in a picturesque valley, surrounded by hills, and about five hundred feet above the level of the sea. This region of the country is known, on account of its mountainous character, as the "Switzerland of Normandy." The springs are mildly mineralized and have a temperature of 65° F.; 10,000 parts contain only 1.309 of solids. There are also several cold chalybeate springs in the place.

ACCESS.—From Paris to Domfort, thence to the village of Couterne, which is about six miles from the springs.

ANALYSIS.—Besides chloride of sodium, small quantities of arsenical salts, sulphides, silica, lithia salts, and

baryum are contained in these waters; also a moderate proportion of carbonic acid gas.

INDICATIONS.—Chronic sores, phlebitis, skin diseases, scrofula, chlorosis, rheumatism, abdominal plethora, and gastralgia, are the diseases said to be beneficially affected by a course of these waters.

ACCOMMODATION.—Modern bathing establishment, with the usual appliances. Moderately good lodgings at boarding houses. *Edmund C. Wendt.*

BAGNOLS-LES-BAINS.—A watering-place in the Department of Lozère, France.

LOCATION.—Bagnols-les-Bains is situated in a narrow valley at an elevation of about two thousand six hundred feet above the level of the sea. The climate is rather trying on account of sudden atmospheric changes. There are six hot sulphurous springs with temperatures ranging from 50° F. to 105° F. Season, June to September.

ACCESS.—Paris to Mende, on the Paris, Lyons & Mediterranean Railroad (fifteen hours). From there by stage to Bagnols in three hours.

ANALYSIS.—The springs are only slightly mineralized, the chief ingredients being sulphate of soda, carbonate of soda, and sulphides.

INDICATIONS.—The diseases usually treated here are cutaneous affections, scrofula, rheumatism, chronic ulcers, etc. But it is at least open to question whether cardiac and pulmonary complaints, for which the springs are also recommended by French physicians, would not be made worse there, on account of the known uncertainties of the climate.

ACCOMMODATION.—There are two thermal establishments, with the usual facilities for douches, sprays, inhalations, etc. Hotels moderately good and cheap. *Edmund C. Wendt.*

BAINS-LES-BAINS, a quiet watering-place in the Vosges Mountain district, with springs highly prized by the Romans.

LOCATION.—Bains-les-Bains is pleasantly situated in a wooded district of France, near the town of Epinal. Elevation above sea-level, nine hundred feet.

Mr. Wolff, in "The Watering-places of the Vosges" (London, 1891), thus speaks of it: "Thanks to the meeting of two different geological formations—the granite of the Vosges on one side, and the calcareous stretch of Champagne on the other—the climate of this intervening sandy belt is also said to be all that could be desired, inimical to disease, and remarkably conducive to longevity. Proceeding to more minute local features, the new hotel seems, in respect of construction, tolerably perfect. There are airy, good-sized rooms. And I was surprised to find of all places this retired and old-fashioned oasis taking the lead among Vosges watering-places in the adoption of the electric light, which is laid on all over the house. The glories of Bains are now obscured, but it has had its halcyon days. In the Roman period it was in its own country, fairly rich in thermal waters, the 'Balneum' *par excellence*, of the bath-loving conquerors. There is a *Bain Romain* still in use, modern of course, but built upon the site of the origiual old Roman *balneum.*"

Dr. Bailly considers the waters of Bains, Plombières, and Luxeuil almost identical in effect, their main constituents being sulphate of sodium and chloride of sodium.

At Bains-les-Bains there are eleven springs in all, by far the most productive and most important—and also the hottest—of which is the *Grosse Source*, which is the property of the State. The next in importance is the *Source Tiède de la Promenade*, which indicates from 82° to 86° F.; and the third is the *Robinet de Fer*, a very weakly mineralized water, having but 0.35 gramme of solids in the litre, which is almost, if not quite, as hot as the *Grosse Source.*

ACCESS.—From Paris, viâ Mulhouse to Epinal, thence by omnibus or carriage.

ANALYSIS.—In one thousand parts:

	Grosse Source. Parts.	Source de la Promenade. Parts.	Source de la Vache. Parts.	Source Savonneuse. Parts.
Sulphate of lime.....	0.110	0.075	0.102	0.160
Chloride of sodium....	0.083	0.058	0.136	0.163
Carbonate of soda....	0.010	—	—	—
Carbonate of lime....	0.028	0.018	0.018	0.045
Silica.....	0.069	0.047	0.093	0.221
Oxide of iron..... ...	0.002	0.002	0.002	0.002
Organic matter.....	Trace.	Trace.	Trace.	Trace.
	0.302	0.700	0.351	0.491
Temperature.....	122° F.	88–95° F.	99° F.	99–107° F.

INDICATIONS.—There are two thermal establishments, with the usual appliances for douches, sprays, etc. The complaints for which the waters are prescribed are, above all things, articular rheumatism, chronic and acute, and sciatica, and then gout, rheumatic gout, liver complaints, obstruction and tumors, paralysis, cutaneous diseases, fractures, contusions, and the like. Constantin James—referring, it is to be presumed, more particularly to the tepid *Source de la Promenade*, which is especially credited with this effect—speaks of them as at the same time tonic and soothing to the nervous system. It should be borne in mind, however, that the climate of Bains is decidedly variable.

ACCOMMODATION.—The newly built *Grand Hotel* is comfortable and commodious. There is a *Casino* under the same roof, a theatre, concert-room, card-rooms, etc. There are many pleasant shaded walks in the vicinity. Season, May to October. There are also several less pretentious and more moderate hotels, as well as a variety of lodging-houses. *Edmund C. Wendt.*

BALARUC-LES-BAINS.—A watering-place in the Department of Hérault, France.

LOCATION.—Balaruc is near Cette and Montpelier, not far from the Mediterranean Sea, and on a peninsula projecting into the Talu. It is only slightly elevated above the sea-level, but the little valley is healthy and enjoys an agreeable climate. There is a saline spring having a temperature of 116° F., and flowing very abundantly.

ACCESS.—From Paris to Cette on the Paris, Lyons & Mediterranean Railroad, thence by carriage to Balaruc.

ANALYSIS.—In 10,000 parts of the water there are found:

	Parts.
Chloride of sodium.....	68.02
Chloride of magnesium.....	10.74
Sulphate of potassium.....	0.53
Sulphate of magnesium.....	0.43
Sulphate of lime.....	7.55
Carbonate of lime.....	3.05
Bromide of sodium.....	0.03
Bromide of magnesium.....	0.32
Silica.....	0.13
Total solids.....	90.80

Taken in quantity this water acts as a purgative, and it has even been observed that the bowels may remain loose for some time after the termination of a course of treatment. The water is also largely exported.

INDICATIONS.—Scrofula, struma, paralysis, rheumatism, metallic intoxications, anchylosis, and chlorotic conditions are said to be quite successfully treated at Balaruc. Patients suffering from paralytic conditions dependent on hysteria should, however, not be sent there. Although the place is a warm one, the principal thermal establishments are closed during the winter season. There is a large military bathing-place, maintained by the French Government.

ACCOMMODATION.—The thermal establishments are not as perfectly comfortable and modern in appliances as could be desired. But the usual douches, sprays, etc., are administered. Amusements are only sparingly provided, and "bath-life" is decidedly dull at Balaruc. Fashionable throngs avoid it. *Edmund C. Wendt.*

BARÈGES. A much-frequented watering-place in the *Hautes-Pyrénées*, France.

LOCATION.—The village of Barèges is situated in a narrow valley, formed by the Bastan. It is 4,000 feet above the level of the sea, and is thus the most elevated of the spas in the Pyrenees. The surrounding mountains are barren, and the spot has no particular natural charms to recommend it. There are, however, some nine or ten mineral springs, which have given the village its great reputation as a health-resort. The French maintain a military thermal establishment there. Harsh climate.

ACCESS.—The village is thirty miles from Tarbes, and is reached by a tedious road. Pierrefitte is the nearest station on the Bordeaux Railway.

ANALYSIS.—According to Louchamp, one quart of the waters contains:

	Grains.
Sulphate of sodium	0.649
Sulphuret of sodium	0.771
Chloride of sodium	0.618
Silica	1.034
Lime	0.030
Magnesia	0.005
Caustic soda	0.077
Caustic potash	traces
Ammonia	traces
Total solids	3.184

The temperature of the ten springs varies from 85° F. to 112° F. The water is clear, but has a disagreeable odor and taste, often producing nausea and vomiting.

INDICATIONS.—Barèges enjoys an excellent reputation in the treatment of chronic diseases, such as indolent ulcers, caries, necrosis, skin diseases, syphilis, and old rheumatism. The waters, being stimulating and exciting, should not be used in acute troubles, in debilitated people, in cardiac troubles, and anæmia. Season, June to September.

ACCOMMODATION.—Only passable, owing to the fact that the number of foreigners visiting the springs is not large. Hôtel des Princes is the principal hotel.

Edmund C. Wendt.

BARMOUTH. A popular English sea-side resort, said to be suitable even in winter (?) for phthisis. The place is situated on Cardigan Bay, and with Aberystwith (farther south), belongs to a group of favorite British resorts on the west coast of Wales. The climate is alleged to be equable, dry, and mild, and while it is exposed to westerly breezes, there is good protection from the harsh north and east winds. The proximity to the splendid mountain scenery of Wales contributes to the popularity of these places. The bathing is good, there being a fine sandy beach, with a gradual descent. Good drinking-water, and sanitary arrangements. Season in the early summer. The place is reached from London (Euston) in about eight hours. *Edmund C. Wendt.*

BENZANILIDE (Phenyl-benzamide). This is one of the three anilides that have proved active medicinally. The others are salicylanilide and acetanilide. In benzanilide the salicylic acid or acetic acid of the others is replaced by benzoic acid. It is obtained by the action of benzoyl chloride or of benzoic acid on aniline, in chemically equivalent proportions, at the boiling-point. It occurs in small, white, shining scales, tasteless, odorless, insoluble in water, soluble in alcohol, 1 in 60. It is chemically and therapeutically allied to acetanilide. Kahn and Hepp, when investigating antifebrine, used it in a number of cases and found it to possess similar properties. Dose, two to ten grains. The advantages claimed for it are that it possesses less toxic properties and after its use the rise of temperature is more slow.

Beaumont Small.

BERTRICH. A spa in Rhenish Prussia, often spoken of as the "mild Carlsbad on the Moselle."

LOCATION.—The "Königliches Bad Bertrich" is insufficiently known outside of Germany. Dr. Greenwood appears to be about the only English author who has hitherto mentioned the place. Dr. Rieth, who is the Royal Bath Physician at Bertrich, informed the writer, at San Remo, that only quite recently were the claims of this spa to an assured place among the continental resorts being recognized beyond the limits of Germany. In the *British Medical Journal*, August 8, 1891, Dr. Greenwood has briefly alluded to this watering-place as follows: "Bertrich is about five miles from Alf, on the Moselle. It is situated in a deep ravine among richly wooded hills. The valley of the Alf, with its numerous side branches, is one of the most beautiful on the Moselle. Bertrich is now becoming more than a local health-resort, as it is more accessible than formerly. It possesses two thermal springs, giving a large supply of water (92° F.), and having a composition similar to that of Carlsbad. It is, however, much less concentrated, not altogether a disadvantage, as in the opinion of Dr. Lauder Brunton the amount of water consumed is a very important factor in the treatment of certain diseases. Particularly is this the case in biliary concretions, a class of diseases which derive marked benefit from treatment at Bertrich. The town possesses good hotels and boarding-houses, the charges being exceedingly low. There are daily open-air concerts. Reunions and other entertainments are also freely provided." From Dr. Rieth I gather that the mountain air of Bertrich is pure and bracing, although the place is only 500 feet above the level of the sea. The climate is equable.

ACCESS.—The interesting towns of Trier and Coblenz are only a little over one hour's ride by rail from Bertrich. The station for Bertrich on the Moselle Railway is Bullay, and a good carriage road leads in less than one hour to the spa. Steamers also ply between Alf, Trier, and Coblenz.

ANALYSIS.—For purposes of comparison the analysis of the Bertrich thermal water is placed side by side with those of Carlsbad and Marienbad.

In 1,000 parts of Water:	BERTRICH. Trink-oder Bergquelle (R. Fresenius and E. Hintz, 1890).	CARLSBAD. Mühlbrunnen (Ragsby, 1862).	MARIENBAD. Ferdinandsbrunnen (Kersten).

(See Chemische Untersuchung der Trink-oder Bergquelle des Königl. Bades Bertrich. Wiesbaden, 1891.)

INDICATIONS.—Most diseases of the stomach are said to do well at Bertrich. The following morbid conditions are also treated with good results there: Abdominal plethora, hepatic affections, lithæmia, diabetes mellitus, obesity, and, finally, various nervous affections of the neurasthenic type. Catarrhal affections of the upper air-passages are also included in the rather large category

of complaints treated at Bertrich. Season, May to the end of September.

Accommodation.—There are a number of hotels managed on the German plan, and a few apartment and boarding-houses. There are pleasant walks and drives, and the management is now liberal in the way of providing amusements. Nevertheless Bertrich is still rather "quiet and dull." There is a *Kurhaus*, and the thermal bathing establishments are excellent. For patients of limited means, who need a mild Carlsbad treatment, a course at Bertrich may be advised. *Edmund C. Wendt.*

BETA-NAPHTHOL BENZOATE ($C_{10}H_7O$, C_7H_5O). Obtained by the reaction that takes place between beta-naphthol and benzoic acid. It is a whitish, crystalline powder, very slightly soluble in water, freely soluble in chloroform and alcohol.

It is recommended as a substitute for betol, having the advantages that benzoic acid possesses over salicylic acid. When introduced into the intestines it breaks up into beta-naphthol and benzoic acid. The former remains in the intestines until excreted by them; the latter is absorbed and eliminated with the urine.

The dose is from four to seven grains, frequently repeated. *Beaumont Small.*

BETOL. The beta-naphthol ether of salicylic acid, analogous to salol, which is the phenyl ether of salicylic acid. It is obtained by the reaction between beta-naphthol and salicylic acid in the presence of a dehydrating agent. It forms in small, white, brilliant crystals, almost devoid of taste and odor. Insoluble in water, soluble in alcohol and oils. Betol possesses antiseptic and antipyretic properties. It is not acted on in the stomach, but when it reaches the alkaline fluids of the intestines it breaks up into beta-naphthol and salicylic acid. It is recommended as a substitute for salol in rheumatic affections, cystitis, intestinal catarrh, etc. It has the advantage over salol of being composed of less toxic constituents. The dose is from five to eight grains. In combination with salicylate of bismuth it is particularly recommended in the treatment of the summer diarrhœa of children and in typhoid fever. *Beaumont Small.*

BEX. A popular thermal and climatic station in the Canton of Vaud, Switzerland. Famous "*salines.*"

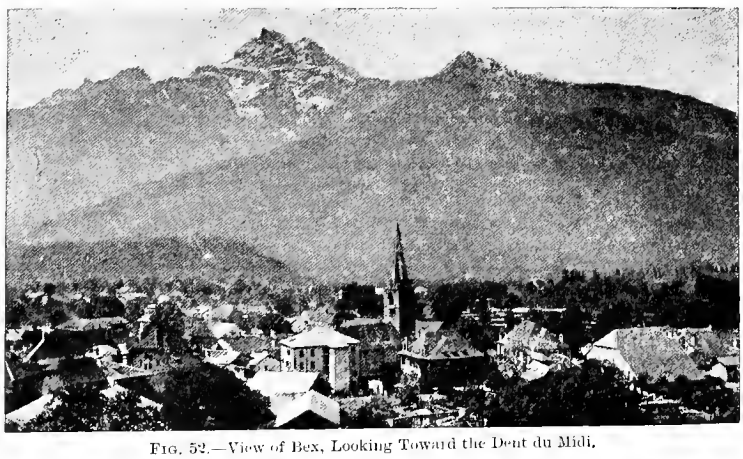

Fig. 52.—View of Bex, Looking Toward the Dent du Midi.

Location.—Bex is beautifully situated in an expansion of the Rhône Valley, and at no great distance from Vevey, on the lake of Geneva. It is 1,400 feet above sea-level. The little village is well known in Europe, but only very slightly in America. The writer, having spent several seasons at this resort, knows it to deserve greater recognition than has been hitherto accorded to it in our country. The "salines" themselves are of no mean importance, and the principal bathing establishment is a modern and commodious one. As for milk-, whey-, and grape-cures, there are few places where these can be more advantageously taken than at Bex. Invalids have also rare opportunities there for beautiful walks through a charming landscape, and, for the more hardy, distant mountain excursions offer strengthening recreation.

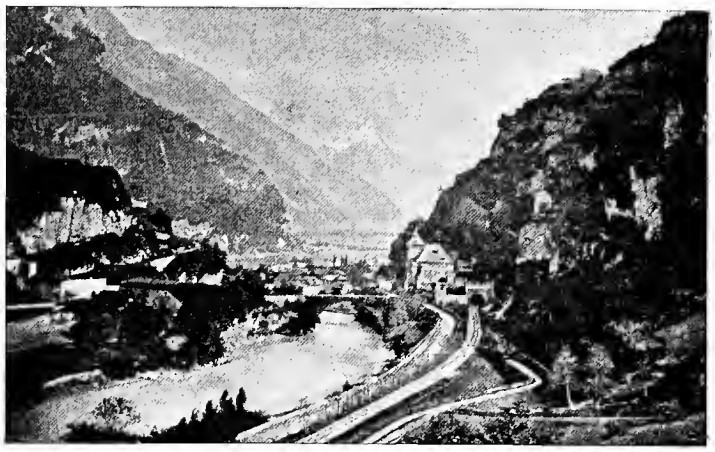

Fig. 53.—The Valley of the Rhône, near Bex.

Access.—Bex is a station on the railroad running through the valley of the Rhône. The village and Grand Hotel des Salines are reached by carriage or stage in fifteen minutes. From Paris the route is *vid* Geneva.

Analysis.—The brine is conducted to the bathing establishment from the distant salt-mines. Ten litres of the brine contain (Bischoff) 1,703 gms. of solids.

The principal ingredients, in ten thousand parts, are:

	Parts.
Chloride of sodium	1567.0
Chloride of potassium	26.5
Chloride of magnesium	10.8
Sulphate of lime	67.6

Ten to twenty quarts of this brine are used for a bath. The diluted brine is also employed internally, after having been charged with carbonic acid gas. It contains, in addition to the salts mentioned above, a small proportion of iodides and bromides.

Indications.—Apart from its advantages as a climatic resort, specially emphasized by the late Professor Lebert, Bex is now recognized to be an important bathing station. The climate is about that of Montreux, although, in spite of its mountain-protected position, harsh blasts occasionally sweep through the valley. The annual mean of the temperature is about 50° F.

The following class of cases do well at Bex: Scrofula in all its manifestations, rheumatism in its subacute forms, catarrhal affections of the air-passages, paretic and paralytic states after diphtheria and other infectious diseases, asthma, neurasthenia of the milder type, and the earlier stages of phthisis. Certain uterine affections, such as metritis, subinvolution, etc., are also benefited by a mild course of the baths. All patients in whom even moderate stimulation of the nervous system is liable to do harm should be warned

against using the Bex treatment. The thermal establishment is thoroughly equipped with inhalation cabinets, sprays, douches, and the usual outfit for hydrotherapy. The quality of the grapes used for the cure is excellent.

ACCOMMODATION.—The *Grand Hotel des Salines* is an excellent establishment of its kind, situated at some distance from and about 150 feet above the village proper. In the latter very reasonable and fairly good board is obtainable. The *Pension du Crochet* is a popular family hotel on a small scale. *Edmund C. Wendt.*

BILIN. A watering-place in Bohemia, where the famous "Sauerbrunn," or "cold Vichy," is found.

LOCATION.—Bilin is only two miles south of Teplitz-Schönau, the oldest watering-place in Bohemia. It is situated in the fertile valley of the Bila. The town has 6,000 inhabitants. The famous castle of Lobkowitz is located in this place. Over three millions of bottles of this saline water are annually exported, but it is not a largely frequented resort.

ACCESS.—Bilin is now a station on a branch line of the Bohemian Railway.

ANALYSIS.—In one thousand parts of the Bilin water there are contained:

	Parts.
Sodium carbonate	3.363
Sodium chloride	0.381
Sodium sulphate	0.719
Magnesium carbonate	0.171
Lithium carbonate	0.010
Carbonate of lime	0.410
Total solids	5.054
Free carbonic acid gas	1.409

The springs have a temperature of 53° F.

INDICATIONS.—Catarrhal conditions, Bright's disease, gravel, gout, diabetes, obesity, hemorrhoids, dyspepsia, and many affections of the genito-urinary system are said to derive benefit from a course of these waters.

ACCOMMODATION.—There is a *Kurhaus*, several hotels and boarding-houses. *Edmund C. Wendt.*

BISKRA. A new winter resort, in the province of Algiers, Africa. According to Dr. Madison Taylor (the *Climatologist*, November 15, 1891), Biskra is an oasis at the north edge of the desert of Sahara. The author named gives the following account of this new place: "Here the fashionable world, especially the French-speaking *monde* and those who follow in their wake, claim that they have found the most charming place wherein to spend the winter. They have already stimulated capitalists to build handsome, thoroughly equipped hotels there, and the tide of fashion is steadily setting that way. It may be briefly described as the terminus of the railroad running south from the great ports on the North African coast, the chief of which are Algiers and Philippeville. From either harbor railroad communication is to be had, *viâ* Constantine, to the very edge of the desert, Biskra. Here is the centre of the various caravan routes across the Sahara." Among the attractions "the charm of Oriental scenes" is mentioned.

"As to the climatic advantages of all this region, it need only be said that it is sufficiently high, being practically on the sides of the Atlas Mountains, to enjoy all the atmospheric charm of elevated table-land. Near by, on many sides, are snow-capped mountains throughout the bulk of the year. Southward the enormous expanse of sand absorbs and retains the heat of the tropical sun, over which almost no cloud passes throughout the entire year. In the immediate neighborhood of the mountains, however, local vapor condensations occur, and showers are numerous enough at certain times; but the characteristic of the climate is steady, uniform, dry warmth. The elevation of the place modifies this to just about the proper degree. There is, then, a practically uniform climate throughout the year. It is not only dry, but bracing, at no time cold, and only in midsummer unbearably hot as the equatorial rays become completely vertical. The season is, therefore, a long one; the possibility of malaria almost *nil*, because of the intensely drying properties of the vast volume of sun-heated, sand-reflecting desert air. In the valleys there is a little verdure in some places, very charming to behold, the sight of which, seen here and there on looking down upon the desert oases, inexpressibly gladdens the eye. Among the charming possibilities of the place are visits on horseback to other oases lying near by."

ACCESS.—Biskra is now accessible from Gibraltar, from Marseilles, or from Genoa. The North-German Lloyd steamers sailing to Genoa stop at Gibraltar. From Marseilles the voyage to Algiers is only a little over twenty-four hours. *Edmund C. Wendt.*

BLACKPOOL. A popular seaside resort in Lancashire, England. It is situated to the north of the estuary of the Ribble, about sixteen miles west of Preston by rail. It can be easily reached from Manchester and Liverpool. Dr. Yeo ("Climate and Health Resorts") gives the following account of this place: "Blackpool has no protection to speak of, and lies fully open to the westerly winds which prevail on this coast. It has a fine seaport, bracing air, and miles of good sands for bathing." The sanitation, drinking-water, and provisions for amusements are quite satisfactory. Season, May to October. *Edmund C. Wendt.*

BLOOD-STAINS. In the examination of stains upon weapons, clothing, or other objects, in medico-legal cases, the objects have often been partly washed or subjected to influences which render identification difficult and sometimes impossible, especially when the quantity of material for examination is small. The methods of examination by the guaiacum test and by the spectroscope have been fully treated in the article on Blood-stains in Vol. I. of the HANDBOOK.

The micro-chemical examination of stains to produce *hæmin crystals*, or crystals of hæmatin, or Teichmann crystals, when only minute stains are to be examined, is so important that we deem it desirable to give the following directions, which we have translated from "Précis de Médecine Légale," by Ch. Vibbert:

"The Teichmann crystals are so characteristic that when once seen they are afterward easily recognized. The operations for obtaining them are exceedingly simple, but require great care and patience. To avoid failure, persons but little accustomed to these minute investigations should follow carefully the methods here described, especially if, as often happens, only minute portions of the suspected material are available for these researches.

"(*a*) *Solution of the Stain.*—If the stain is small and no speck or clot to be removed can be seen, cut out the stain, following the edges of the stain, with scissors; place the stained piece of cloth on a glass slide, and put on it a few drops of water, just enough to moisten it, for it is better to get a solution somewhat concentrated After maceration till the liquid is considerably colored, press out the liquid with a scalpel or a needle, and remove the cloth, leaving the colored fluid on the slide. Avoid spreading the liquid, but dry it slowly so that it shall make a small, deeply colored spot on the glass, not entirely opaque but somewhat transparent, so that the preparation can be examined with the microscope.

"If the stains are very small several may be taken and macerated together to obtain sufficient coloring matter for the subsequent manipulations. If the stain is on wood, a thin layer of the wood may be removed with a sharp knife or lancet, and treated as directed for a fragment of cloth, only the maceration should be continued much longer.

"If it is not possible to lift the stain from the object, a ring of wax may be formed around it, making an enclosure that will hold a little water, which may be applied to absorb the stain. When the water has absorbed the coloring matter, it may be transferred to a slide by means of a pipette.

"(*b*) *Evaporation of the Liquid.*—We may allow the liquid to evaporate spontaneously, but it may be hastened by heat, only it is necessary to heat it very moderately, not exceeding a temperature of 60° Centigrade; for if the

heat is sufficient to coagulate the albumin it will interfere with the production of crystals. We generally warm the slide over the flame of an alcohol lamp, being careful that the temperature does not exceed that which is not uncomfortable when the slide is laid upon the back of the hand. It is important to heat the liquid around the borders and not in the centre, so as to prevent the liquid spreading over the slide, which would much interfere with subsequent operations.

"(*c*) *Action of Reagents.*—To the evaporated residue a little common salt should be added. Too much is injurious. It is better to make a solution of 1 part of chloride of sodium with 500 or 1,000 of distilled water, and add one or two drops of this solution. It is *more convenient to use this solution in the first place for dissolving the stain*, instead of using simple distilled water. It saves time and nothing is changed. Sometimes crystals can be obtained by treatment with acetic acid without the addition of salt, there being sufficient chloride of sodium in the blood, but it is better to add the salt than risk a failure in an important case.

"In whatever part of the process the chloride of sodium has been added, the preparation must be thoroughly dried afterward before the acetic acid is applied. This acetic acid monohydrate is called glacial or crystallizable. (It solidifies at the freezing-point, or zero Centigrade, and does not again liquefy until the temperature is raised to 17° Centigrade.) The addition of a small quantity of water transforms it to acid hydrate, which interferes with this reaction.

"Place a drop of the acetic acid monohydrate on the preparation and evaporate with heat, which may be increased and continued, but which succeeds better if it does not quite reach the boiling-point. When there is but a small quantity of the suspected material, it is especially important to use all these precautions. The acid should be taken up with a tube drawn out to a fine point, so that only a very small drop may be added at a time; place the droplet in the centre of the red deposit on the slide, and allow it to spread a little, but not to spread beyond the limit of the stain; for this purpose the heat of the lamp should be applied around the borders at various points, tipping the slide as may be necessary to retain the fluid on the red deposit only; a red line is thus formed about the borders when the coloring matter becomes thickened, and the acid remains on the stain till evaporation is completed. It is on this border that the crystals are commonly formed, and they are to be looked for by aid of the microscope.

"It is not common to find crystals after adding only a single drop of acid, but it is generally necessary to add drop after drop, evaporating each with the greatest care, examining the specimens from time to time where the red lines are formed one after the other as it is repeatedly treated with acid and dried. When this experiment is performed under favorable conditions, a multitude of distinct crystals are found. Often, however, we find only irregular masses of brown or dark coloring matter, and the remainder of the preparation filled with coagulated albumin and foreign bodies, which have become mixed with the stain. If we have added solid particles of chloride of sodium to the coloring matter, we are apt to find crystals of this salt formed in cubes, in stars or small, colorless globules, and even lance-shaped crystals of acetate of sodium may be formed. All these crystals, arranged together in beautiful forms, may often be found.

"In such cases, we select a point where the coloring matter is collected in considerable quantity, and there apply another small drop of acid and let it evaporate as before. By repeating this operation we sometimes obtain a large collection of very small crystals mingled with other matter, but when we find crystals in the form of a cross or in stars, it is very certain that they are chlorohydrate of hæmatin, and we may perfect the preparation by the addition of small drops of acetic acid.

"If doubt still remains in regard to the nature of the crystals, the specimen should be examined by the aid of polarized light. The albuminous or saline substances allow the field to remain dark, but the crystals of hæmatin appear bright on a dark field.

"By carefully following the precautions stated above, one can almost always obtain crystals of hæmatin, even with a very minute quantity of blood. The reaction is successful with very old stains. Many experts have obtained crystals of hæmatin from stains of blood ten, fifteen, and even forty years old. It sometimes happens, however, that it is impossible to obtain crystals when the stains are only a few months old. This is especially the case when the blood has been allowed to putrefy before drying. Contact with perspiration, grease, or tannin also appears to interfere with the formation of crystals.

"*Two sources of error* are to be noticed in connection with this test for blood. Crystals of murexide (purpurate of ammonia) have a form very similar to crystals of hæmatin, but they are of a bright red, and they acquire a violet color by contact with a solution of potash; but it is very difficult to imagine how it can be possible to obtain crystals of murexide by treating a stain with common salt and acetic acid. A mistake may easily occur with crystals formed from indigo. Cloth colored with this material will sometimes furnish a deposit of crystals, which will not dissolve in acetic acid and which have a form very similar to crystals of hæmatin. Their color is blue, it is true, but when the color is very deep it can scarcely be distinguished from brown. Descoust, by simply washing with water a piece of flannel of blue-violet color obtained crystals of the form and reddish-yellow color almost exactly like crystals of hæmatin. This is a more serious cause of error than is generally admitted in books on legal medicine.

"When a stain to be examined is found on clothing colored with indigo, it is important before examining the stain itself to examine pieces of the garment which are not stained to see whether they will deposit crystals of indigo. The comparison between these crystals and those obtained from the stain may remove all uncertainty if, for example, the crystals obtained from the stain are very numerous, and those obtained from the unstained cloth are very few and of a blue color. If the similarity of the two species of crystals is very close we may try the guaiacum test. The crystals of hæmatin will color the guaiacum blue, while the indigo has no effect upon it.

"When the crystals of hæmatin have been obtained they may be preserved for an indefinite period by adding a little glycerine and covering the preparation with thin glass. The expert should preserve the preparation with care as a proof of the correctness of his conclusions."

Microscopic Examination. — In the examination of blood-stains it is found that some of the corpuscles are more easily separated from the clot than others. Where the stain shows specks of dried clot which can be separated from the fabric they are more likely to resume their normal form and size than when the stain is thinner; yet single corpuscles can often be found here and there on threads or on fibres of wool, cotton, or silk. If a few drops of a solution of iodine or of eosine are added to the solvent the corpuscles are more likely to remain visible. The chief difficulty is, that any solvent which will liberate the corpuscles from the fibrin will at the same time dissolve the coloring matter of the corpuscles and render them so transparent that they are practically invisible.

Stains upon weapons of iron or steel are often so mingled with rust that great difficulty is encountered in recovering the corpuscles. If the colored substance, supposed to consist of rust mingled with blood, is placed upon a slip of glass and a drop of dilute hydrochloric acid added, the acid will dissolve the rust and sometimes bring to view the blood-corpuscles, which may be measured before they are destroyed by the acid.

It often happens, where the stain is old or very minute, that while corpuscles may be identified, the hæmoglobin is so changed or decomposed that no absorption bands can be seen in the microspectroscope, and no hæmin crystals can be obtained by treating with acetic acid and chloride of sodium. So also the stain, if old, will gener-

ally be so changed that the number of corpuscles to be seen and measured is small compared with what might otherwise be expected from the extent and color of the stain.

Since my article on blood-stains was written, in 1885 (see vol. i., pp. 575–589), increased attention has been given to this subject by medico-legal writers, and modernized views have been published, mingled with much that was written before the great improvements in the microscope revolutionized the work of medical experts. Professor John J. Reese, M.D., in the second edition of his "Text-Book of Medical Jurisprudence," 1889, says, p. 132: "Given a skilled and careful microscopist, with a good instrument of proper amplification, it will generally be possible to diagnosticate a human blood-stain from that of any of the lower animals, with the possible exception of the guinea-pig and opossum. (We exclude, of course, those few animals, more rarely met with, whose corpuscles are larger than the human, viz.: the elephant, great ant-eater, walrus, whale, sloth, and capybara.) It will always be possible absolutely to distinguish between human blood and that of the ordinary domestic animals—the ox, pig, horse, sheep, and goat—with which it is most likely to be confounded."

In apparent opposition to the above quotation from the Professor's book we find in the *Medico-Legal Journal* of New York, for September, 1892, a letter from Professor Reese, addressed to the editor, Clark Bell, Esq., in which he says:

"Certainly (as stated in Taylor's) there is no difficulty in detecting corpuscles much smaller than $\frac{1}{4000}$ of an inch, as, *e.g.*, those of the horse, sheep, and goat. The present general idea seems to be that while it is admitted that a skilful microscopist can certainly distinguish between a human corpuscle and one of a horse, cow, pig, sheep, and goat (domestic animals with which it would be likely to be confounded), still, in a murder trial, where human life is at stake, the expert is hardly warranted to swear that the blood is anything more than that of a mammal."

The proper bearing of the above statement we shall consider below.

In "The Law of Expert Testimony," by H. W. Rogers, A.M., LL.D., St. Louis, Mo., 1891, we find much that is interesting on the subject of blood-stains. Brief abstracts of testimony in the famous Cronin case are given.

The most important for our purposes are the views of Professor Marshall D. Ewell, M.D., who testified in that case, giving his opinion "that in the present state of science it was impossible to determine in the case of a specimen of dried blood by the measurement of the blood-corpuscles anything more or further than the mere fact that it was the blood of some mammal." He said: "I am very decidedly of the opinion, judging from my experience, that in the present state of science it is impossible to determine certainly, even under the most favorable circumstances, that any given specimen of fresh blood is human blood."

In the *Medico-Legal Journal*, September, 1892, p. 178, Professor Ewell claims that the possible imperfections of micrometers which have not been carefully tested by a common standard may account for the different average dimensions of blood-corpuscles as reported by different observers. Also that the personal equation of the observer causes a difference in the results as shown by samples reported. Third, that measurements by the Jackson micrometer, when low powers are used, are less accurate than measurements by the filar micrometer, but that with high magnifying powers there is little difference in accuracy between the Jackson micrometer and the filar micrometer.

Next, Professor Ewell shows that there are appreciable differences in the average dimensions of blood-corpuscles taken from the same person on different days, and in different circumstances; and, further, that the average diameter of the human blood-corpuscle is greatly affected by different diseases.

Lastly, that when blood has been dried on weapons, clothing, or other objects, and exposed to unknown conditions, there is no certainty that any treatment will restore the corpuscles to their normal diameter, so as to allow an expert to determine from what animal the blood was derived.

From the above considerations, illustrated by careful observations reported in his paper, Professor Ewell formulates the following conclusions:

Summary (by Professor Ewell).—"(1) The only proposed methods of identifying blood that are worthy of discussion are (a) Teichmann's process of obtaining hæmin crystals; (b) the guaiacum test; (c) the spectroscopic test; (d) the microscopic identification of red blood-corpuscles; and (e) the micrometric test. The last method only will be here discussed.

"(2) In the use of the micrometric test no confidence can be placed in the result, unless the errors of the micrometer used, with reference to some authentic standard, are known.

"(3) Where the subject continues during a *short* period in substantially the same condition of good health, there appears, in the hands of the same observer, to be an average size of the *fresh corpuscles*, provided at least one hundred corpuscles are measured.

"(4) There are such large discrepancies between the averages obtained from the measurement of the *fresh* blood-corpuscles of animals of the same species, and between measurements of the same objects by different observers, as to throw doubt upon the published results. Several tables of measurements are given (by Professor Ewell) to prove this statement.

"(5) There is no advantage in using very high power in such investigations.

"(6) Drying the blood-corpuscles in a clot multiplies the difficulty of identification. It has never been proven that dried corpuscles can be restored to their normal proportions.

"(7) The mean size of the red corpuscles of very young animals is larger, and their size varies between wider limits, than in adults.

"(8) Many diseases alter the size of the red corpuscles; especially is this so in microcythæmia.

"(9) Fasting diminishes both the size and number of the red blood-corpuscles. So also in the case of various drugs.

"(10) In view of the foregoing it is impossible in the present state of science to say of a given specimen of blood, fresh or dry, more than that it is the blood of a mammal."

As the paper by Professor Ewell, of which the above are his conclusions, has been largely quoted in the third edition of Reese's "Medical Jurisprudence," and as Professor Ewell is now the most prominent opponent of medical experts on blood-stains, the above conclusions will be examined in detail.

As a general proposition Professor Ewell's statement (it will be readily admitted) that no certainty of accurate measurement can be claimed unless we have micrometers graduated and tested by some acknowledged standard, is true, yet it is a remarkable fact that the measurements of human blood given by Gulliver, in 1875, $\frac{1}{3200}$; Wormley, in 1885, $\frac{1}{3260}$; Schmidt, in 1848, $\frac{1}{3300}$; French Medico-Legal Society, in 1873, $\frac{1}{3267}$; Masson, in 1885, $\frac{1}{3267}$; Hans Schmid, in 1878, $\frac{1}{3412}$; Woodward, in 1875, $\frac{1}{3092}$; Formad, $\frac{1}{3200}$, made at distant intervals and without comparison by a common standard, differ by less than one-sixth of the difference between the blood of man and that of the pig.

This objection does not apply to comparative measurements of blood of different animals, where the expert, using always the same micrometer, bases his diagnosis on his own measurements alone. At present, however, it is easy for the expert to obtain micrometers made by skilful workmen and carefully rated by comparison with a reliable standard.

In regard to the discrepancies noticed by Professor Ewell between the measurements of blood-corpuscles made by different observers, it is to be noticed that the different writers fail to state whether they measured from outside to outside of the dark border of the corpuscle, or

whether, like Dr. Woodward, they measured from the centre of the dark border on one side to the centre of the dark border on the other side, or whether they rejected the whole of the dark border on both sides, considering that as only a shadow and not a part of the corpuscle. We claim that the whole of the dark border on both sides is to be measured. This we have proved by grinding glass disks in the form of the corpuscle, with rounded edges, and examining such disks with the microscope. We have also studied the blood-corpuscle by reflected light, by means of Beck's patent illuminator, measuring it with the micrometer when no dark border was shown, and then with transmitted light again measuring the same corpuscle. In both conditions the measurement was the same.

Another source of difference in measurement is in the mode of obtaining and preparing the blood for measurement. If a string is tied around the finger or the circulation is impeded in any other manner, and the blood is obtained by pricking with a needle, and is then spread upon a slide, the corpuscles, deprived of a portion of serum, will measure less than if obtained from a cut with a lancet where the circulation is not obstructed.

So also, if the blood is drawn from the prick of a needle in a warm and dry atmosphere, the corpuscles begin to contract before they can be spread upon a slip of glass.

None of these considerations enables us to reconcile all the discrepancies noticed by Professor Ewell in the writings of different authors; but the great fact is shown, by the unanimous consent of all microscopists, so far as we can ascertain, that less than three thousand five hundred (most writers say less than three thousand three hundred) corpuscles of human blood are required to measure an inch, when placed side by side; while more than four thousand corpuscles of the pig are required to measure an inch, and for the horse, ox, cat, sheep, and goat still more are required. Hence all authors agree that there is a remarkable difference between the average diameter of the human blood-corpuscle and that of any domestic animal except the dog.

Taking the pig as the representative of domestic animals, because its corpuscles are larger than those of the ox, horse, cat, sheep, or goat, the following comparison between the blood of the pig and human blood is very significant.

To determine the extent of the possibility of mistaking the blood of the pig, ox, horse, sheep, or goat for human blood, we will examine the table of measurements made by J. B. Treadwell, M.D., using a $\frac{1}{25}$-inch objective made by R. B. Tolles, and Jackson's Eye-piece Micrometer, made by Tolles, ruled by Professor Rogers, and a stage micrometer ruled, tested, and rated by Professor Rogers.

In this table the measurements of 3,000 corpuscles are given, 200 having been taken from each of fifteen different persons. The measurements are given maximum and minimum by tens, by twenties, by fifties, and by one hundreds, and by two hundreds. Six hundred corpuscles from pigs were measured, 200 from a pig three weeks old, 200 from one of two months, and 200 from a pig three months old.

As the corpuscles of the pig have a larger average than those of the ox, horse, sheep, or goat, we make our comparison between the blood of man and the blood of these three young pigs.

	Mikrons.		Mikrons.
Man, smallest ten	7.658	Largest ten	8.298
Pig, " "	5.418	" "	6.520
Man, smallest twenty	7.662	Largest twenty	8.191
Pig, " "	5.757	" "	6.466
Man, smallest fifty	7.768	Largest fifty	8.079
Pig, " "	5.880	" "	6.246
Man, smallest hundred	7.852	Largest hundred	8.046
Pig, " "	6.028	" "	6.169

	Mikrons.
Smallest ten from man	7.658
Largest ten from the pig	6.520
Difference	1.138

This equals 0.000045 of an inch = $\frac{1}{22222}$ inch.

	Mikrons.
Smallest twenty from man	7.662
Largest twenty from the pig	6.466
Difference	1.196

This equals 0.000047 of an inch = $\frac{1}{21276}$ inch.

	Mikrons.
Smallest fifty from man	7.768
Largest fifty from the pig	6.246
Difference	1.522

This equals 0.000060 of an inch = $\frac{1}{16666}$ inch.

	Mikrons.
Smallest hundred from man	7.852
Largest hundred from the pig	6.169
Difference	1.683

This equals 0.000066 of an inch = $\frac{1}{15151}$ inch.

We thus see that where only ten corpuscles are measured in man, taking the smallest average of ten consecutively measured, this average for an adult man is one-sixth larger than the largest average of ten consecutive corpuscles measured from a young pig only three weeks old; while the average of the smallest one hundred from man, taken consecutively, is about one-fifth $\frac{1}{7\frac{6}{8}}$ larger than the largest one hundred taken from the young pig.

I fully agree with Professor Ewell that there is no advantage in using very high powers in measurement of blood-corpuscles. By this is meant that for actual work and careful measurements a magnification of 1,000, or at most 1,500, diameters is quite as good as the use of higher powers. Beyond this limit increased enlargement is obtained at the expense of clearness of outline. Mathematical demonstration proves that the apparent thickness of the object increases as the square of the apparent diameter increases. (See Naegeli and Schwendenef on the Microscope; also Carpenter on the Microscope, edited by Dallinger.)

I have no controversy with those who have used powers of 3,000 or 4,000 diameters; I have myself photographed blood-corpuscles with about 4,000 diameters linear, but the results are no better than with an enlargement of 1,500 diameters.

Gulliver's measurements were made with powers of about 600 diameters and yet they present but insignificant variations from the work of the latest observers, who have used magnifying powers of 2,000 to 3,000 diameters.

Professor Ewell's sixth proposition is apparently, more than all the others, the one on which he depends for support of his final conclusions. He says: "Drying the blood-corpuscles in a clot multiplies the difficulty of identification. It has never been proven that dried corpuscles can be restored to their normal proportions."

I would call attention again to the table on p. 587, Vol. I. of the HANDBOOK, giving the measurements of 3,000 corpuscles of fresh human blood, including males and females, of all ages, from infants at birth to the man of seventy. The measurements are in mikrons.

Number of individuals.	Number of corpuscles.	Average.	Max. Min.	By 10s.	By 20s.	By 50s.	By 100s.	By 200s.
15 persons as stated.	3,000	7.938	4.233 10.160	7.658 8.298	7.662 8.191	7.768 8.079	7.852 8.046	7.913 7.983
Blood-stains, human.	1,000	7.910	5.570 9.687	7.700 8.184	7.723 8.010	.....	.....	.....
3 young pigs.	600	6.101	3.849 8.391	5.418 6.520	5.757 6.466	5.880 6.246	6.028 6.169	6.069 6.144

Here we see that the average of 1,000 corpuscles restored and measured from stains of human blood is 7.910 mikrons, all probably being stains from the blood of adults; while the average from fifteen persons (three being infants) is 7.938 mikrons. The maximum, where infants are included, in fresh blood is a little more widely separated from the minimum than in the restored stains from adults. So also the range, when taken by

tens or by twenties, is a little less for restored blood than for fresh blood, for the same reason. No closer similarity of results could have been expected had all the measurements been taken from fresh blood; one set including infants and the other being taken from adults alone. The fact that there is this difference given above goes to show the great accuracy and perfect restoration of dried blood-corpuscles to their normal dimensions.

As a further confirmation of the possibility of restoring dried blood-stains to a condition in which their dimensions can be properly compared with fresh blood-corpuscles, I copy by permission the following table from Professor Wormley's "Micro-Chemistry of Poisons."

Examination of Old Blood-Stains.

Animal.	Age of stain.	Remarks.	Average.	Fresh blood.
			Inch.	Inch.
(1) Human	2 months old.	Stain, unknown.	1-3358	1-3250
(2) Human	2½ " "	Stain.....	1-3236	1-3250
(3) Human	3 " "	Stain.....	1-3354	1-3250
(4) Human	19 " "	Clot.....	1-3290	1-3250
(5) Elephant...	13 " "	Clot.....	1-2849	1-2738
(6) Dog.....	4 " "	Trace of stain unknown	1-3626	1-3561
(7) Rabbit	18 " "	Clot.....	1-3683	1-3653
(8) Ox	16 " "	Stain.....	1-4544	1-4219
(9) Ox	32 " "	Stain, unknown.	1-4495	1-4219
(10) Ox	4½ years "	Clot.....	1-4535	1-4219
(11) Buffalo	18 months "	Clot	1-4312	1-4351
(12) Goat	17 " "	Stain.....	1-5897	1-6189
(13) Ibex	18 " "	Clot.....	1-6578	1-6445

"In the case of the human blood No. 1, two months old, the deposit was in the form of a thin stain on muslin, and its nature, other than that it was mammalian blood, was unknown at the time of examination. The corpuscles were readily found, and two series of thirty corpuscles were measured. In the human blood two and a half months old, fifty corpuscles ranging from $\frac{1}{3125}$ to $\frac{1}{3448}$ of an inch, were measured.

"The blood-stain of the dog, No. 6, was prepared by Dr. Frankenberg, and consisted of a single stain so minute as to be barely visible to the naked eye; its nature at the time of the examination was unknown. In this instance only fifteen corpuscles were measured. In the ox blood four and a half years old, the corpuscles were rather readily obtained, and two closely concordant series of measurements were made."

Another table, quoted by Clark Bell, Esq., in his article on "Blood-Stains" in the *Medico-Legal Journal*, September, 1892, p. 157, is worthy of careful study in this connection. It shows results of examinations of blood dried on knives, glass, wood, cloth, paper, and stone, with measurements corresponding very closely with measurements of fresh blood.

I take great pleasure in acknowledging my obligations to Professor Ewell, from whose valuable articles on micrometric study of 4,000 red blood-corpuscles, published in the *Medico-Legal Journal* for September, 1892, I have compiled the following table:

Source of Blood.	Number of corpuscles.	Mean in Mikrons.	Maximum.	Minimum.	By hundreds Maximum.	By hundreds Minimum.
Robust man.....	650	8.03	9.98	5.03	8.28	7.95
Boy thirty-six hours old.....	200	8.86	11.39	5.70	9.06	8.65
Adult man.....	100	7.85	9.32	6.73	....	....
Purpura hæmorrhagica	200	8.26	10.87	3.45	8.28	8.25
2 cases pseudo-leucocythæmia.	400	8.04	11.04	6.56	8.55	8.42
Tuberculosis anæmic	100	8.35	10.70	5.35	....	....
Plumbism	100	8.65	10.10	5.18	....	...
Gastritis.....	100	8.32	10.18	6.22	....	...
2 cases syphilis.....	200	8.11	9.32	3.97	8.11	8.11
Erysipelas	100	7.83	9.15	6.90	....	....
Pernicious anæmia	100	7.69	9.93	6.04	....	....
Menstrual blood	100	7.71	8.80	5.76	....	....
Whole number measured...	2,350	8.14	11.39	3.45	9.06	7.95

If we take $\frac{1}{3200}$ of an inch or 7.937 mikrons as the generally accepted average diameter of human blood-corpuscles, and with it compare the average obtained by Professor Ewell from blood in disease, we find his largest average in plumbism, or lead-poisoning, is 8.65 mikrons, or one-twelfth part larger than the normal average.

Now, if we take the young pig, which, excepting the dog, is the domestic animal having the largest corpuscles, and to the normal average, 6.101 mikrons, add one-twelfth its diameter, or 0.508 mikrons, we shall obtain for a possibly diseased pig an average diameter of 6.609 mikrons; smaller by 1.318 mikrons than the average human blood-corpuscle. Certainly no microscopist of ordinary skill would be in any danger of confounding blood of such a diseased pig with human blood recovered from a stain.

The only remaining possibility of mistaking stains from blood of a pig, ox, horse, sheep, or goat for human blood, when fifty or one hundred corpuscles have been measured and found to average 7.9 mikrons, or even 7 mikrons, is to suppose it possible that the expert has *wickedly* and *purposely* measured only the largest corpuscles and has not done honest work. With a magnifying power of 1,000 diameters, a Jackson's micrometer measures with great certainty to $\frac{1}{50000}$ of an inch. Professor Ewell's filar micrometer, as he states, is graduated to one millionth of an inch, and is certainly reliable to $\frac{1}{50000}$ of an inch. Hence, no expert can have any difficulty in recognizing with absolute certainty differences of 1.3 mikrons equal $\frac{1}{200000}$ of an inch.

Professor Ewell says that, "by selecting the corpuscles, it would be possible for a dishonest observer to make the average much larger or smaller than the above given (in his table) without the possibility of detection; a fact, the bearing of which upon the value of expert testimony upon this subject is so obvious as to need no comment." I have never claimed, and shall not now claim, that it is any more difficult for a witness to swear falsely in regard to blood-stains than in regard to any other subject. But it would be quite possible on cross-examination to ask the expert whether, in measuring the corpuscles obtained from a stain, he had measured all the well-defined corpuscles in the field of the microscope, or whether he had selected the large corpuscles and rejected others which were smaller.

In treating blood-stains with solvents of fibrin, to liberate the corpuscles for measurement, it has been found in many cases that the corpuscles were smaller than in fresh blood unless maceration was long continued, old stains requiring several weeks before the corpuscles were in a condition to be measured. When a biconcave blood-corpuscle is placed in water, the coloring matter (hæmaglobin) is dissolved out, the corpuscle swells up, thickens at the edges, becomes transparent and spherical. In this condition the diameter of the corpuscle becomes less than normal. It thus happens in examining blood-stains that all corpuscles which have lost their color or have become spherical are by some experts rejected and not measured. Some corpuscles in fresh blood have much more coloring matter than others, and these corpuscles retain their color and form (as we think) much longer than paler corpuscles. We are not aware that any fluid used or likely to be used for softening blood-stains will cause the corpuscles to become larger than normal.

If the corpuscles obtained from a stain do not recover their normal dimensions it is almost absolutely certain that their average measurement will be less than normal and *never* greater than normal. Thus, in the language of Professor Wormley, we may confidently say: "*Thus, then, while the blood of man might on account of contraction in diameter of the blood-corpuscles be confounded with that of some animal having smaller corpuscles, the reverse could never occur.*"

From this discussion I claim that it has been proved beyond any reasonable question:

(1) That in favorable cases blood-stains can be so treated that reliable measurements and credible diagnosis of their origin can be given, as shown in the tables given and in others which might be referred to.

(2) That if error occurs on account of imperfect resto-

ration of the form and diameter of the corpuscles obtained from a stain, proved (by, *a*, the guaiacum test; *b*, the spectroscope; *c*, by the production of hæmin crystals) to be blood, the error, if any, will be to make human blood appear like that of one of the inferior animals, and never to mistake the blood of the ox, pig, horse, sheep, or goat for human blood.

(3) In general, when a stain has been proved to be blood by the above tests, it may be decided certainly whether it is or is not mammalian blood. So, also, a stain from the blood of the ox, pig, horse, sheep, and goat may be distinguished from human blood, thus confirming the claim of an accused person in many cases that his clothes are *not* stained with human blood. This negative testimony is certainly quite as important in many cases as testimony inculpating a prisoner.

Lastly, the expert can say, when the average of a suitable number of corpuscles from a blood-stain corresponds with the average of fresh human corpuscles, that the stain is certainly not from the blood of the ox, pig, sheep, or goat.

Such testimony by a skilled microscopist is of untold importance in saving the lives of the innocent, and often in overthrowing the plea of those who are guilty. Such testimony is quite as reliable and important to the welfare of society as that of the chemist who testifies to the presence or absence of poison that might have some resemblance to the many recently discovered ptomaïnes.

The testimony of the expert might take the following form, as recommended by C. H. Vibbert, "Précis de Médecine Légale:"

"This stain is *not* composed of the blood of such an animal (ox, sheep, horse, pig, or goat) as the accused claims. It is like the blood of man, or some animal having corpuscles very nearly the same size as those of man, as the dog or rabbit."

Or the declaration may take the reverse form, thus: "This stain is *not* composed of human blood; it might be the blood of a horse, ox, pig, sheep, or goat, as claimed by the accused."

Such declarations are justified, then, and then only, when the examination has been conducted with great care and the measurements have been made with reliable instruments. *Moses C. White.*

BOCKLET. A thermal station near Kissingen, Bavaria, much frequented by patients from Kissingen.

Location.—This little village is only a few miles, in a northerly direction, from Kissingen. Its strong chalybeate springs are often used by patients taking at the same time a course of treatment at the larger spa. Its climate is mild, and it is a simple little village, affording more quiet and cheaper comforts than are obtainable at the crowded spa of Kissingen.

Access.—By carriage or on foot from Kissingen. Stages run between the two places.

Analysis.—In one pint there are contained:

	Grains.
Carbonate of iron	0.67
Carbonate of lime	0.54
Carbonate of magnesia	3.60
Chloride of magnesium	4.43
Chloride of sodium	6.55
Sulphate of sodium	4.54
Sulphate of magnesium	3.23

The spring is also very rich in free carbonic acid gas.

Indications.—Anæmia, chlorosis, neurasthenia, diseases of women, especially when associated with tendency to constipation. Diabetics are also said to be benefited there.

Accommodation.—There is a *Kurhaus*, small hotels, and a number of boarding-houses, all moderately good. *Edmund C. Wendt.*

BONE TRANSPLANTATION. One of the most interesting of the various fields opened up since the advent of aseptic and antiseptic surgery is that of grafting and transplanting tissues from one part to another of the same or different animal or person. The success with which this can be done in the case of the skin is well known. Failure is the exception. Far different is the result when other tissues are made use of. Experiments with muscle, nerve, and tendon transplantation are, in almost all cases, failures; very few successful cases have so far been reported. As regards the results, osseous tissue occupies a position midway between these two groups; the skin on the one hand, and muscle, nerve, and tendon on the other. While in the case of certain bones the results are so favorable that bone transplantation is constantly employed, in others only isolated successful cases are reported. As a result of a large series of experiments, Adamkiewicz (*Centralblatt für Chirurgie*, 1889, Nos. xi. and xxxviii.) reaches the following conclusions: Pieces of bone, from one-half to three-fourths centimetre in diameter, unite perfectly well when they are replaced after having been removed, as by trephining. The pieces can lie exposed to the air or in a two to three per cent. carbolic acid solution, five or ten minutes without impairing the result. Larger pieces, over one centimetre in diameter, also unite perfectly well, even when the edges are not entirely smooth. Bony union takes place where osseous structures come in contact and the interstices are filled with a fibrous tissue. There is no need of taking any special care that the edges fit accurately. The surfaces of the transplanted bone retain their original form and smoothness. He claims that the periosteum takes no necessary part in the process; that the same results are obtained by transplanting pieces entirely stripped of their periosteal covering. The highly cellular connective tissue filling in the interspaces later becomes ossified, either by separate centres of growth, or by the ossification proceeding from the periphery inward, until union is complete. The amount of space which may thus be bridged over is not stated, but probably it is not very great.

These results hold good, not only for the same individual or another of the same species, but also when the bone is taken from entirely different species.

Moisson ("Thèse de Paris," 1892), from a very thorough study of the literature of the subject, comes to practically the same conclusions as Adamkiewicz. Both of these authors base their conclusions on studies and experiments connected chiefly with the cranial bones, and so far as those are concerned there is no doubt as to their correctness. The great activity in brain surgery the past few years has furnished large numbers of cases for clinical experimentation in this line. If the disk removed be small it may be replaced entire, and in the great majority of cases bony union will result. When the chisel is used, the chips may be strewn over the dura, and they usually adhere and live. Large buttons may be cut up and used in the same way. In case there is too large a defect to be covered by the bone in hand, pieces may be taken from the front of the tibia, or even from animals, with a very fair prospect of success. In some cases, however, the implanted bone is absorbed after a time, and in others it becomes necrosed and has to be removed.

Ollier read a paper before the International Medical Congress in Berlin, in 1890 (*British Medical Journal*, August 16, 1890), giving the results of his very extensive experience in this branch of surgery. He divides these operations into three classes, first, the autoplastic, in which the same bone is used to repair some deficiency in itself, and the bone is only partially severed from its connections; second, the homoplastic, where the graft is taken from the same individual but not from the same bone; and third, the heteroplastic, where the bone is taken from another individual or animal. He says the first and second methods are all but failures, and the third quite so, that is to say, the implanted bone could never grow. He further says it is perfectly hopeless to expect any permanent or complete growth of bone, unless the periosteum surrounds it. It is, indeed, true that if the parts were aseptic for a time the new bone or implanted bone, as the case might be, seemed to grow, but this was only for a time. Within six months necrosis takes place and the dead bone if loose, is thrown out, or

it may remain encysted in some instances, and while it may do no harm it is certainly of no advantage to its possessor. Notwithstanding what has been said to the contrary, he says there is no exception to this rule. These statements, coming as they do from such an authority as Ollier, carry great weight with them, yet they are at variance with the experience of most surgeons. As regards trephining, as we have seen, the mass of evidence is against them, and aside from these there are a large number of isolated cases of bone transplantation reported which tend to refute at least his final remark that there is no exception to the rule of failure. P. Berger (*Gazette des Hôpitaux*, January 14, 1892), reports a case where he successfully covered the defect due to spina bifida by a piece of bone taken from the shoulder-blade of a young rabbit. Almost every surgeon has had one or more successful results from re-attaching ends of digits entirely severed.

For the purpose of replacing the loss of the nasal bones or cartilages, transplantation of animal bone is sometimes successful. I have under observation now one case where two years ago I elevated the nasal bridge by the introduction of four cat-ribs under the skin. Thus far the bridge is solid and firm, and has not sunk in.

In another case where there was a sinking in from loss of the alar cartilages, a perfect elevation was procured by splitting the alæ and introducing flat pieces of bone taken from the front of the tibia. In a third case, to obtain the desired result, part of the shoulder-blade of a cat was used. All of these operations were done over a year ago, and the bone is still retained and is firm and solid, and there is no irritation. In only one case have I had to remove the transplanted bones. Necrosis in this case was, I think, due to the pieces being kept in a 1 to 1,000 bichloride of mercury solution by mistake. However, even then it was found that at the ends they were so firmly united as to require considerable force to extract them. That the bone was living and healthy at the ends, was shown by the shreds of living tissue adhering to them, and by the healthy pink color of the transverse section.

A very interesting experiment is reported by Phelps (New York *Medical Record*, February 21, 1891). In order to repair an ununited fracture of the leg of a boy, he inserted a portion of the leg bone of a dog, which was kept in connection with the animal until union had taken place. There was primary union of the soft parts, but unfortunately he was obliged to sever the graft on the eleventh day, owing to its becoming loosened from the muscular twitching. There was free oozing of blood from the cut surfaces, showing that circulation had become established between the patient and the dog. At the end of five weeks, no union having taken place, the graft was removed. It showed on its surface new formation of bone, and the medullary cavity was partially filled with new bone. The operation was a failure, and yet it seems as if more extended experiments in the same direction might lead to useful results.

In conclusion, it may be said that while, with few exceptions, the results obtained by bone transplantation are by no means satisfactory, yet they are such as to encourage a more extended trial. The most rigid asepsis rather than antisepsis should be employed in all these operations. The pieces of bone should be as small as will serve the purpose, several small pieces doing better than one large one, and where it is possible bony contact should be secured. If it be impracticable to replace or transplant the pieces immediately, they should be kept in a warm sterilized salt solution rather than in antiseptic fluids.

It is only by the most careful attention to all the details that a successful result can be secured.

William Barnes.

BORMIO. An ancient thermal station in the upper Valtellina district of Lombardy, Italy, now chiefly patronized as a climatic resort.

Location.—Bormio is situated near the river Adda, surrounded by massive rocks and precipices, and something like 4,000 feet above the level of the sea. The thermal waters are indifferent gypsum springs, and have been described by Pliny. The season is a short one, being restricted to the months of July and August, although the climate of Bormio is possibly a trifle more equable and mild than that of the Engadine, near which the place is situated. There is a barren and sombre look to the landscape at Bormio, but the village leads to some points where grand mountain views may be enjoyed.

Access.—By railroad as far as Botzen, then on through Meran, and over the Stelvio Pass; or by way of Como, and up the valley of the Adda; or through Coire, and then by "diligence" up the mountains.

Analysis.—There are eight springs, issuing from the calcareous precipices, near the foot of the Monte Brauglio. There is an abundance of water, something like 300 gallons a minute. The springs are hot, up to 120° F.

Analysis of the San Martino Spring at Bormio.—Ten thousand parts of water contain:

	Parts.
Chloride of sodium	5 112
Sulphate of sodium	0.604
Sulphate of potassium	0.181
Sulphate of magnesium	2 520
Sulphate of lime	4.863
Carbonate of lime	1.735
Carbonate of iron	0.025
Carbonate of manganese	0.014
Silicic acid	0.207
Total solids	10.261
Carbonic acid gas	0.474

Indications.—Gout, rheumatism, cutaneous affections, hepatic and splenic disorders, hysteria, and scrofula are the principal diseases treated at this mountain resort.

Accommodation.—The old thermal establishment *Bagni di San Martino* is rather primitive, but the new building, lower down and near the village, is a modern institution, where all the appliances for inhalations, massage, hydro-therapy, gymnastics, etc., are found. Milk- and whey-cures. Terms moderate. The old road over the Stelvio Pass into the Tyrol passes through Bormio.

Edmund C. Wendt.

BOULOGNE-SUR-MER. A French sea-side resort, largely frequented by the English.

Location.—Boulogne-sur-Mer is a fortified seaport of the Department Pas de Calais. It is on the shore of the English Channel, at the mouth of the river Lianne. It consists of two parts, the Old Town, located on the hill, and the New Town, along the water. Daily communication by steamboat with England, *viâ* Folkestone. The beach is fine. The town is a fishing centre, and is dirty but interesting. There is also a chalybeate spring not much used. Bathing is on the French system. The town is half English.

Accommodation.—Several good hotels, and a vast number of poor ones. There is a *Casino*, where plenty of gambling goes on. Also a theatre, concert-halls, etc. It is no longer a fashionable resort, being mostly frequented by the middle classes. It is a favorite place for excursions from England, and resembles our own Coney Island in many respects. *Edmund C. Wendt.*

BOURBONNE-LES-BAINS. A watering-place in the Department of Haute Marne, France, the Aquæ Bormonis of the ancients.

Location.—Bourbonne is an attractive little place, surrounded by hills and mountain spurs of the Jura formation. Mr. Wolff says of it, in his interesting work on the Vosges watering-places: "As in its geological position, so of course in the character of its waters does Bourbonne differ very materially from the other 'Watering-places of the Vosges.' Its springs are strongly mineralized, containing over seven grammes per litre of solid matter, and very hot—much hotter than anyone could bear their application. People who have accidentally dropped into this water, in which an egg is thoroughly boiled in fourteen minutes, are reported to have become in a few minutes so thoroughly flayed as to bring on death. Of the medicinal effects of the waters there has

never been any doubt. It seems a veritable bank of Bethesda. Along it hobble and limp, and are wheeled and carried, halt, lame, and cripples, people bent double with rheumatism, palsied with paralysis, misshapen with deformity—scrofulous, pale, and delicate children. Bath-chairs and crutches and sticks appear to be the rule rather than the exception."

Bourbonne is 850 feet above sea-level. Its climate is not equable and rather relaxing. Dr. Macpherson has called it the French Wiesbaden. Dr. Yeo says life is simple and cheap there. The French State maintains a thermal establishment here, chiefly used by military invalids. Few foreigners make use of the baths, although the place is attracting more attention now than formerly.

Access.—From Paris there are through trains in seven hours. From other places the local branch line and omnibuses are used, but are inconvenient.

Analysis.—In 1,000 parts :

General Analysis.

Silica	0.0604
Carbonate of lime	0.0751
Carbonate of magnesia	0.0035
Carbonates of iron and manganese	0.0038

Carbonic acid (free)	0.0703
Carbonic acid (in combination)	0.0263
Silica	0.0748
Carbonate of lime	0.0743
Carbonate of magnesia	0.0032
Carbonates of iron and manganese	0.0023
Fluoride of calcium	tracea
Sulphate of lime	1.3980
Chloride of calcium	0.0785
Chloride of magnesium	0.0538
Chloride of lithium	0.0887
Chloride of sodium	5.2020
Chloride of potassium, rubidium, and cæsium	0.1992
Bromide of sodium	0.0644
Iodine, arsenic, and ammonia	traces
Total	7.3358

Temperature 149° Fahrenheit.

Indications.—The waters being hot bromo-iodurated saline ones are useful in rheumatism, scrofula, paralysis, engorgement of abdominal viscera, and certain forms of neuralgia. Dr. Macpherson holds them to be curative in rebellious malarial fevers. Mr. Wolff says that bathing combined with douches, and often electricity, forms the basis of treatment. Massage is not held in excessive estimation, and the local doctors consider that their *douches de haute pression*—for which the water is pumped up to a height of 54 feet—are fully equal in effect to any rubbing and shampooing. Electricity, is however, much resorted to, especially in the Military Baths—which form an entirely distinct establishment, locally separated from the general *Thermes*—where, in the officers' annex, model appliances for its use may be seen. Of their douches the Bourbonne people are exceedingly proud, and they employ them in every form, from the finely divided *pulvérisation* up to the heavy jet which, one would think, would have sufficient force almost to knock a man down. Drinking is not prescribed for everyone, and rarely exceeds a daily dose of two or three tumblers. A course of treatment at Bourbonne lasts from three to four weeks.

Accommodation.—The Hotel des Bains is a good hotel. The bathing establishments are fitted up with the usual requirements. There are luxurious private baths and cheap general baths. There are amusements in moderation, but the place is not in any sense a fashionable spa ; real invalids intent on being made well are its chief visitors. There is a typical French *Casino*, adjoining the Civilian Thermal Establishment. Numerous French officers and soldiers enliven the scene by their pretty uniforms. *Edmund C. Wendt.*

BOURBOULE (*La*). One of the most important spas in France, although less frequented than the more neutral but fashionable resorts. The springs are strongly arsenical.

Location.—La Bourboule is in the Department of Puy de Dôme, in one of the prettiest regions of Auvergne. The district is very mountainous and the village is situated about 2,700 feet above the level of the sea. It is only five miles from Mont Dore ; it is less shut in than that resort. The hills in the immediate vicinity are of comparatively gentle slope. The mountain climate is on the whole mild, though rather changeable. The springs furnish hot arsenical waters.

Access.—From Paris, on the Paris, Lyons & Mediterranean Railroad, *viâ* Clermont, to Laqueille ; thence, in an hour and a half, by carriage to Bourboule.

Analysis.—One litre of the water contains :

	Grammes.
Arseniate of soda	0.0284
Chloride of sodium	2.8406
Chloride of potassium	0.1623
Chloride of lithium	traces
Chloride of magnesium	0.0320
Bicarbonate of soda	2.8920
Bicarbonate of lime	0.1905
Sulphate of soda	0.2084
Peroxide of iron	0.0021
Oxide of manganese	tracea
Silica	0.1200
Alumina	traces
Organic matter	traces
Carbonic acid (free)	0.0518

Indications.—La Bourboule has a wide range of applicability and enjoys a growing reputation, probably in part due to an energetic and intelligent management. The springs are now controlled by a stock company.

Dr. Yeo states that the waters may be taken with advantage in the following conditions :

1. In anæmic and chlorotic girls and weakly children with scrofulous tendencies, or who are convalescing slowly from surgical operations, especially when undertaken in connection with scrofulous diseases of the bones or other organs, and particularly in those cases in which the preparations of iron prove inefficacious or unsuitable.

2. In herpetic eruptions of the skin and in eczema and psoriasis.

3. In affections of the throat and respiratory passages, especially when found associated with a tendency to cutaneous eruption. In granular pharyngitis, chronic laryngitis, and asthma. In slow forms of chronic phthisis, associated with a tendency to glandular affections ; but it is not to be recommended in cases with a tendency to hæmoptysis or to troublesome dyspepsia.

4. In certain forms of intermittent fever which resist the ordinary forms of treatment.

5. In chronic rheumatism, especially in those very troublesome cases known as cases of "arthritis deformans."

6. In the gouty dyscrasia when there is no tendency to acute attacks.

7. In diabetes, especially in emaciated subjects in whom the waters of Vichy or Vals have been inefficacious, and particularly if the disease be associated with eruptions.

Accommodation.—There are good hotels and private lodgings. Besides the large *Établissement des Thermes*, used by the better class of patients, there are three other bathing establishments, thoroughly well fitted up and ably managed. They offer all the appliances of modern times, such as single, sitz-baths, general baths, steam-baths, inhalation and spray rooms, douches of every description, *buvettes*, etc.

All the springs are hot, the Perrière spring having a

temperature of about 125° F. There is a good *Casino*, and the ordinary amusements of French spas. Season, June to October. *Edmund C. Wendt.*

BOW-LEGS. The simplest and most effective brace for the correction of those cases of bow-legs in which the bones may still be bent, consists of a strip of flat bar-iron along the concavity of the curve, an inch longer than the distance from the garter-line to the sole of the shoe. The lower end is forged round, bent at a right angle, and passed into a hole, or a tube, in the heel of the shoe. At the garter-line a padded band is riveted, reaching two-thirds around the leg, and just above the malleoli a like band is attached. The splint applied, the leg is firmly bandaged to the bar.

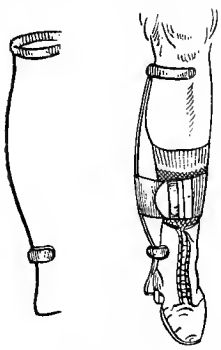

FIG. 54.—The Thomas Bow-leg Brace.

When the deformity has been corrected a broad leather strap may be used in place of the bandage. In cases where the deformity is due in a measure to the laxity of the external ligaments of the knee-joint the brace is carried above the knee, and a posterior bar is added, as in the splint for knock-knee. *John Ridlon.*

BRAIN.* GROSS OR MACROSCOPIC ANATOMY.—§ 1. The primary object of this article is to indicate briefly the principal additions to our knowledge of the subject since the preparation of the article having the same name in Vol. VIII. of the REFERENCE HANDBOOK. But the writer desires first to supply certain omissions in that article, and to correct the errors that have been detected therein. Some of these are obvious and perhaps of no great importance, but others are serious and due to the writer's imperfect observation or interpretation of specimens at that time.†

§ 2. Fig. 4684.—A. Many of the boundary lines are too faintly indicated, *e.g.*, that of the section of the chiasma. A continuous line representing the pia should have surrounded all the cut surfaces in close contact therewith. Another line representing the arachnoid should follow the general contours, as stated more fully in connection with Fig. 4711.

B. The segmental name, *diencephal*, hides most of the oval area indicating the medicommissure ; this last should have been named and should not be dotted ; although it may contain some fibres it consists mostly of cells.

C. The heavy black line representing the endyma should extend farther into the stem (infundibulum) of the hypophysis, as in Fig. 4711. At the second *e* of the abbreviation *mesen* the endymal line should not be interrupted. The interruption opposite the *n* of the abbreviation *meten* represents the metapore (Foramen of Magendie), and should have been so designated as in Fig. 4711.

§ 3. Fig. 4689.—A. On the right (left of the figure) the words *torus* and *lura* should be transposed. The former is the mononymic substitute for *tuber cinereum*, the elevation ; the latter designates the orifice, *foramen infundibuli*, left by the removal of the hypophysis.

B. On the opposite side from the word *preoperculum* a line should extend to the brain parallel with the line from *olfactory crus*.

C. The two crura should be equal in width.

D. The word *vallecula* should be *vallicula*, although the former is commonly used.

§ 4. Fig. 4698.—On the left the numbers 4 and 5 should be transposed.

§ 5. Fig. 4702.—In the upper figure the endymal line should be continuous in the roof of the mesocœle.

§ 6. Fig. 4703.—The area surrounded by the dotted circle should be marked 2 instead of 1. Since it represents the medicommissure, a bar crossing the diacœle (Fig. 4727), it might well have been left blank in this figure of the cast. In the description, near the middle, *top* should be *tip*.

§ 7. Fig. 4711.—In the description, first line, 8 should be .8 ; second line, for *subfalcial*, read *falcial* ; fourth line, for *falciculu*, read *falculu*.

§ 8. Fig. 4715.—A. Near the tip of the temporal lobe, just under the end of the line from *postoperculum*, there is really an independent triradiate fissure, consisting of a stem directed toward the tip of the lobe, with branches extending respectively dorso-caudad and ventro-caudad. The intermediate branch, a continuation of the stem from the place of radiation into the tip of the supertemporal fissure, should be erased.

B. This will leave the supertemporal fissure with a long spur extending caudad and slightly ventrad ; the shorter, darker portion of this spur represents a true branch of the fissure ; the longer, fainter part represents an artificial crack and should be erased.

C. The ventral end of the exoccipital fissure presents a branch extending cephalad and another (12) extending ventrad and slightly caudad. At the point of divergence enters the fissure marked 13 ; the junction of this latter is not deep, as appears, but shallow.

D. Just dorsad of the insula is an apparently simple junction of the subfrontal fissure with the precentral. Really there is a branch from each fissure, and they overlap slightly midway, the subfrontal branch being dorsad ; there is thus a narrow isthmus, as in Fig. 4777, between the branches of the central and precentral fissures.

E. In the explanation, after 14, the word *presylvian* should be *subsylvian*.*

§ 9. Fig. 4728.—At the end of the lowest line, indicating the most dorsal portion of the inverted region, should be the word *postgeminum*.

§ 10. Fig. 4729.—*Proplexus* should be *paraplexus*, and *hypocampa, hippocamp*.

§ 11. Fig. 4731.—The line A, B, C, should have been merely dotted to indicate the planes of section on Fig. 4730.

§ 12. Fig. 4740.—In the explanation, eighth line, for *precornu* read *paracœle*.

§ 13. Fig. 4742.—A. In the explanation, fourth line, for *precornual* read *lateral* or *paracœlian*.

B. In view of the claims of some that natural outlets exist from the paracœle into a subarachnoid space (§ 55, T), perhaps the word *presumably* should be inserted before *artificial*.

§ 14. Fig. 4746.—Compare Fig. 51 and the accompanying commentaries.

§ 15. Fig. 4748.—At the upper left-hand corner, *fossi* should be *fossa*.

§ 16. Fig. 4750.—At the left, second name from the top, for *endyma* read *paratela*. See § 53.

§ 17. Fig. 4751.—A. From the word *medicommissure* a line should reach the light strip just ventrad of the diacœle.

B. Near the tip of the lower line from B the outline of the thalamus is defective.

C. Between the left paraplexus and the tenia the membranous floor of the paracœle is the paratela.

§ 18. Fig. 4760.—On the temporal lobe, just dorsad of the pons, the apparent fissure is an artificial crack.

§ 19. Fig. 4767.—A. The short, vertical fissure between the word *operculum* and the number 1 is merely a notch or superficial branch of the presylvian fissure, the main portion of which lies ventrad of 2 ; hence the

* Exclusive of the Membranes of the Brain, which are treated of in a separate article under the title MENINGES.

† The writer ventures to advise that the changes and corrections indicated be marked in the text or upon the illustrations. A suggestion as to the desirability of prompt or periodical self-correction is offered in his paper, The Morphological Importance of the Membranous or other Thin Parietes of the Encephalic Cavities, *Jour. of Comp. Neurology*, i., p. 201.

* Fig. 4723, the word crus should be prepeduncle.

triangular area (1) is part of the operculum. The preoperculum is (2) and the subsylvian fissure is probably represented by a short indentation, visible only when the postoperculum (3) is removed. From the name *presylvian f.* a line should reach the dark space dorsad of (2). In this connection it may be added that corresponding changes should be made in § 208, D, § 234, E, and § 241, L.

§ 20. Fig. 4778.—The two fissures named *presylvian* and *subsylvian* are probably to be regarded as branches of the former, and the latter is represented by a short one concealed, as in Fig. 4767, by the overlapping postoperculum. The number of the specimen should be 318.

§ 21. Fig. 4779.—As in Figs. 4767 and 4778, the presylvian is to be regarded as having a dorsal branch; the true subsylvian as concealed.

§ 22. Fig. 4784.—The fissure named *supercallosal* is the paracentral; here, as often, the two are continuous.

§ 23. The following verbal changes should be made in the same article:

A. In § 80, *callecula* should be *vallicula;* after it should be added Figs. 4689 and 4716.

B. In § 82, C, *typical* should perhaps be *simple;* seldom, in adult brains, has the writer observed the conditions represented in Fig. 4715.

C. In § 218, the interparietal fissure of Ecker was first called by Turner *intraparietal*, and this name should be used unless, as held by the writer, it is admitted to consist of two integers, the parietal and the paroccipital.

§ 24. *Subfrontal Gyre.*—By an inexcusable oversight the more common name of this functionally important region, *viz., Broca's gyrus*, is not given; but it is employed in other articles, *viz.*, II., 34, and VIII., 206. Since the article was prepared there has appeared Hervé's monograph, "La Circonvolution de Broca," Paris, 1888.

§ 25. *Encephalic Variations.*—In § 63 mention should have been made of the brief account of anomalies of the brain in Krause's "Anatomie," pp. 192–195.

§ 26. *Order of Treatment.*—This will follow the series of definitive encephalic segments from the myel (spinal cord) cephalad.

I. General matters of nomenclature and structure; § 27–29.

II. Metencephal (postoblongata and caudal part of "fourth ventricle"). For convenience the metapore (foramen of Magendie) will be considered in the article Meninges.

III. Epencephal (cerebellum, pons, and preoblongata). The cerebellar ectocinerea (cortex) and entocinerea (dentatum and tectal "nuclei"); §§ 30–38.

IV. Mesencephal (crura and gemina or optic lobes).

V. Diencephal (thalami, etc.).* The medicommissure, conarium, paraphysis, and mesal eye; §§ 39–41.

VI. Prosencephal (cerebrum and olfactory lobes). Rhinocœle or olfactory ventricle, § 42; fornix, § 44; hippocamp, § 45; pseudocœle (fifth ventricle), § 46; indusium of the callosum, § 47; incallosal brains, § 48; relations of thalamus to paracœle (lateral ventricle) in the sheep, etc., § 49; in apes, § 52; in man, §§ 53–55; transitory fissures, §§ 56–59; permanent fissures, §§ 60–78; brain weight, § 79.

VII. Bibliography.

§ 27. *Neuraxis or neuron.*—It has now become a serious question which of these short mononyms shall be employed as a substitute for *cerebro-spinal axis, myelencephalon, etc. Neuron* was proposed by the writer in 1884 (*New York Medical Journal*, August 2, p. 114), and employed in 1885 in addresses before the American Neurological Association (as president), "Paronymy *versus* Heteronymy as Neuronymic Principles," and before the Biological Section of the American Association for the Advancement of Science (as vice-president,) "Educational Museums of Vertebrates;" also in the second edition of "Anatomical Technology." It has been adopted in this sense by Minot, "Embryology," 1892, by Waters (*Zool. Anzeiger*, 1891, p. 362), and others.

* Respecting *thalamencephalon* and analogous terms, see Vol. VIII., p. 529, § 74, note.

But, on discovering in the "Dict. de Medecine" of Littré and Robin (1877) that *neuraxe* had been used (by whom not stated) in the same sense, the writer abandoned *neuron* in favor of *neuraxis*, the presumed Latin antecedent of the French *neuraxe*, and used *neuraxis* in the articles in the HANDBOOK. It likewise has been adopted by several writers. Furthermore, *neuron* has been taken by Waldeyer (*Berliner klin. Wochenschr.*, July 13, 1891) to represent a "nerve-entity," consisting of: (*a*) a nerve-cell; (*b*) the nerve-process; (*c*) its collaterals; (*d*) the end branching;" see the abstract by Alexander Hill in *Brain*, vol. xiv., p. 569. In this sense also it is used by C. L. Herrick, *Jour. Comp. Neurol.*, ii., 137, December, 1892.*

The writer has no prejudice, and trusts the matter

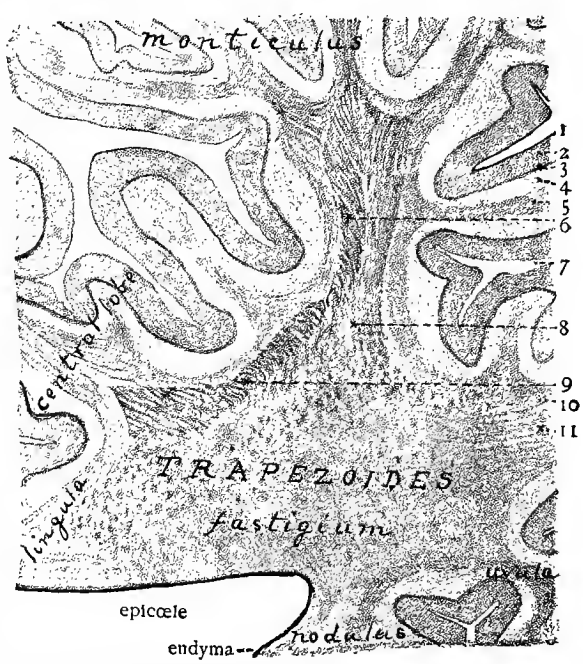

FIG. 55.—The Central Part of the Cerebellum near the Dorsal End of Its Cavity, the Epicœle. From Stilling, Fig. 57a; × 8.

This represents a part of the mesal aspect of the right half of a medisected cerebellum. The entire surface is shown on a smaller scale and without histological differentiation in Vol. VIII., Figs. 4684, 4711, 4718, 4719. In the last the organ is represented approximately erect, *i.e.*, extending dorsad from the oblongata; in the present figure, as in the other three, it is in the natural attitude, tilted caudad, so that the apex of the epicœle looks caudad rather than dorsad.

1. Pia dipping into the rimulas between the foliums; 2, ectal fibrocellular layer of the cortex, neuroglia, etc.; 3, layer of the cells of Purkinje; 4, granular layer; 5, fibrous centre, the alba or medulla; 6, 9, cephalic (anterior) decussating commissure; 7, deep rimula between lobes of the postvermis; 8, cephalic (anterior) branch of the arbor (vitæ); 10, layer designated by Stilling as composed of "guirlandenförmigen Fasern;" 11, caudal (posterior) branch of the arbor.

may be considered by some of the committees on nomenclature for an authoritative recommendation as to usage. It will probably occur to others that *neuron* is a more

* After this article was completed there reached the writer three important papers by His in the Archiv für Anat. u. Physiol., Anat. Abtb., 1892, v. u. vi. Heft., viz., Zur Nomenclatur des Gehirns und Rückenmarkes, pp. 425–428; Die Entwickelung der Menschlichen und thierischer Physiognomien, pp. 384–424; Zur allgemeinen Morphologie des Gehirns, pp. 346–383. The last is profusely illustrated with representations of embryonic brains, mostly of animals. On the first page is a list of terms employed (in gratifying conformity to the suggestion made by the writer in Vol. VIII., p. 528, § 72). The summary is as follows:

"1. Die allgemeine Morphologie des Gehirns eine notwendige Grundlage für die Deutung der Faserbahnen bilden muss.

"2. Eine solche allgemeine Morphologie nur dann endgültig zu gewinnen ist wenn wir auf die allerersten Entwickelungsstufen zurückgreifen. Nur von dieser ersten Anfangsstufe aus lässt sich der Ban sicher aufführen, dadurch dass wir die frühesten topographischen Beziehungen der einzelnen Abschnitte des Markrohres zu einander genau feststellen und dann an der Hand dieser Merkmale die Verwickelung der Formen verfolgen."

natural associate of *axon* and *enteron*, and that it is the legitimate substantive of the adjective *neural*; also that *neuraxis* might very appropriately designate the axis cylinder of a nerve-fibre. Perhaps, however, as with *cilium* (either an eyelash or a microscopic filament), the two uses are not incompatible.

§ 28. *Is there a Rhinencephalic Segment?* — The address by Professor William Turner before the Anatomical Section of the Tenth International Medical Congress, at Berlin, in 1890 (*Jour. Anat. and Physiol.*, xxv., pp. 1–53, with 42 figures), is not merely a valuable and suggestive study in the comparative anatomy of "The Convolutions of the Brain," but also is based upon a recognition of the significance of the fundamental and universal separation of the *pallium*, or strictly cerebral portion of the prosencephal, by a rhinal fissure from the olfactory bulb, crus, and hippocampal lobe, which he includes under the name *Rhinencephalon*.

As may be seen from Vol. VIII. (p. 112, § 15, A; p. 134, § 122), the writer sympathizes with this recognition of the morphological consequence of the olfactory nervous apparatus; but he deprecates the employment of a segmental term like *rhinencephalon* in what is now a third sense. Owen used it for the olfactory bulbs, actually united only in tailless amphibia; the writer (at one time adopting this view) has suggested (Vol. VIII., p. 114, note) that perhaps the bulbs, their crura, the olfactory portion of the precommissure, and a part of the aula, might be recognized as constituting a sixth definitive segment; but—unless the word *encephalon* in composition is to be shorn altogether of segmental significance—it should no more be used for a ventral portion of a region than for a dorsal portion, *e.g.*, the cerebellum, without the supporting preoblongata.*

§ 29. *The Endymal Cilia.*—In Vol. VIII., p. 118, § 43, in stating the simplest expression of an encephalic segment, the constant ental constituent of the parietes, the endyma (*ependyma* of some writers), was mentioned as a ciliated epithelium. There is considerable divergence of statement among authors as to the presence of cilia, especially in adults. P. A. Fish has described (*Amer. Monthly Micros. Jour.*, xi., p. 256, November, 1890) the ciliated cells in the encephalic cavities of the cat, both old and young. He urges the importance of thorough preservation by the injection of the preservative into the cavities; states that a magnification of not less than six hundred diameters must be employed, and intimates that the failure to recognize them in man may be due to defective methods of preparation or examination.

§ 30. *The Cerebellar Cortex.*—In none of the mediseeted brains represented in Vol. VIII. (Figs. 4684, 4711, 4718, 4719) was any effort made to show the thickness or constitution of the cortex of the cerebellar foliums; this omission is in a measure supplied by the accompanying figure (55) from the magnificent work of B. Stilling, "Neue Untersuchungen über den Bau des kleinen Gehirns des Menschen," etc. Q., pp. 357 and lxxviii.; Folio Atlas of 21 plates. Cassel, 1878.

§ 31. Points illustrated by Fig. 55.—A. The triangular form of the apex of the epicœle, whence the term *fastigium* (a gable), applied to its immediate roof.

B. The absence of a layer of cinerea (entocinerea) immediately ectad of the endyma.

C. The non-appearance, upon an accurate medisection, of any of the disconnected masses of cinerea represented in Figs. 56, 57, 58.

D. The irregularly trapezoidal outlines of the medulla (alba) forming the central cone about the apex of the epicœle.

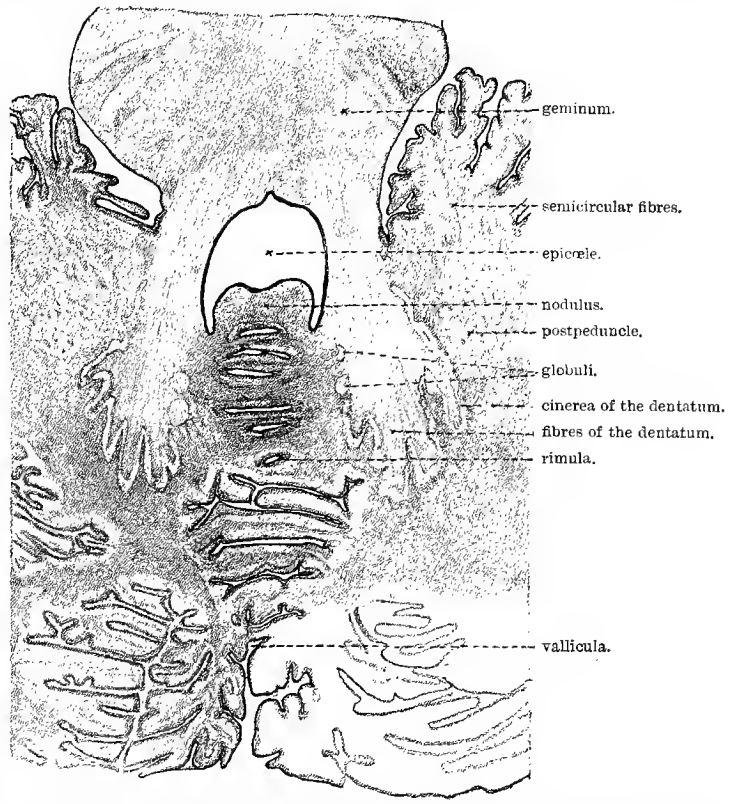

FIG. 56.—The Dentatums and Prepeduncles. From Stilling, Fig. 99, somewhat modified: ×2 –.
Preparation.—The plane of section was oblique, so as to coincide with the general direction of the prepeduncles as shown in Vol. VIII., Figs. 4721, 4722.
Defects.—By an inexcusable oversight the prepeduncles are not indicated by a line and the name; but they are readily recognized as the fibrous tracts at the sides of the epicœle, converging from the dentatums to the geminum. There is no representation of the "fleece," the layer of fibres radiating from the ectal surface of the dentatum; see Edinger's "Twelve Lectures," etc., Fig. 85.

E. The extension of the medulla as branches, whence the more comprehensive name arbor (vitæ) applied to the entire cerebellar alba.

F. The constitution of the cortex by several layers; for their microscopic structure see treatises on the subject.

§ 32. *The Cerebellar Entocinerea.*—In Vol. VIII., p. 128, § 92, brief mention is made of four pairs of masses of cinerea (gray tissue) in the central part of the cerebellum, near the apex of the epicœle; but through a misapprehension they were neither figured nor described in detail. They are commonly referred to as *roof-nuclei*, or *tectal nuclei*.

§ 33. *The Dentatum.*—This is the largest and most easily recognized of the four masses; see Figs. 56, 57, 58. It has the form of a corrugated capsule, open mesoventro-cephalad, for the reception of the fibres of the prepeduncle (Fig. 56). In any cerebellum, whether

* In this connection it may be added that the word *neuromere*, introduced by the writer (*N. Y. Med. Jour.*, 1885, p. 356, and "Anat. Technology," 2d ed., 1886, p. 400[4]) as a mononym for *definitive neural* (or encephalic) *segment*, was adopted in 1887 by Orr (*Jour. of Morphology*, I., p. 335) in the sense of *potential segment*, and this application was accepted by the writer in 1889 (HANDBOOK, VIII., 113, § 23); in this sense it is also employed by Minot ("Embryology," pp. 604–606) and other embryologists.

fresh, or hardened in chromic acid compounds, or even alcohol, it is readily recognized upon transections or upon sagittal sections begun about one centimetre either side of the meson and continued laterad for two or three centimetres.* The dentatum has received the following additional names, of which the last only is used with any frequency: *Nucleus dentatus; corpus denticulatum, s. fimbriatum, s. lenticulatum, s. ciliare;* Eng., ciliary body.

§ 34. *The Fastigatum.*—This, more often called "fastigial nucleus," is close to the meson, directly in the roof (fastigium) of the epicœle; Figs. 57, 58. It is rounded cephalad, but the caudal end presents two or three projections.

§ 35. *The Embolus* and *Globulus.*—These smaller masses of cinerea lie between the dentatum and the fastigium, and somewhat dorsad of the latter. Their forms are indicated by their names, and are well shown in Stilling's figures as reproduced in Figs. 57 and 58. More common (and cumbersome) titles are *Nucleus globosus* or *globuliformis*, and *Nucleus emboliformis.*

§ 36. Points illustrated by Fig. 56.—A. The constitution of the dentatum as a corrugated capsule of cinerea, open cephalo-ventrad.

B. The entrance of the fibres of the prepedunele through the hilum of the dentatum to connect with its cells.

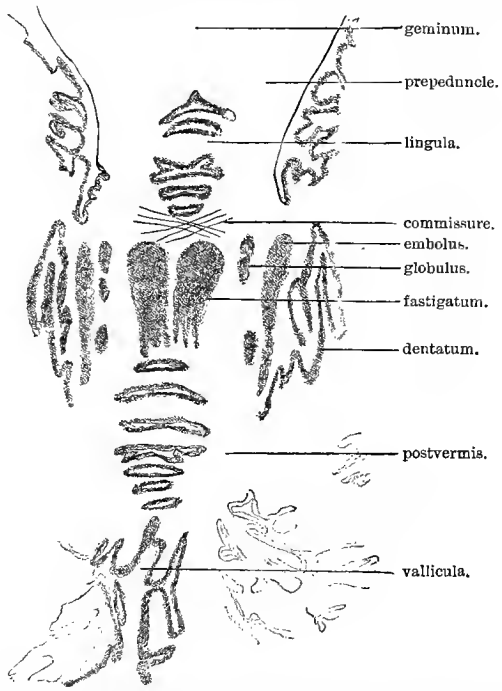

FIG. 57.—The Dentatum and other Masses of Cinerea in the Central Part of the Cerebellum. From Stilling, Fig. 98, somewhat modified; × 2 —.

Preparation.—This is commonly designated as a "horizontal" section. Really, the plane cannot be indicated in such simple terms. The central part of the figure, including the cinereal masses, is through the fastigium, the roof of the apex of the epicœle. Cephalad are parts of the lingula, the prepedunecles, and the mesencephal; caudad the foliums of the postvermis, the mesal vallicula, and parts of the lateral lobes.

Defects.—No attempt has been made to represent the fibrous constitution beyond the purely diagrammatic indication of the cephalic (anterior) decussating commissure.

§ 37. Points illustrated by Fig. 57.—A. The existence, near the apex of the epicœle, of four pair of cinereal masses, representing, perhaps, dislocated portions of the cerebellar entocinerea.

B. The lack of precise symmetry in the forms of these masses; of one set, the globuli, there are three on the left and two on the right, the more cephalic, perhaps, representing the fusion of two.

C. The form of the dentatum as a corrugated capsule with an opening or hilum toward the meson; this is shown better in the following figure.

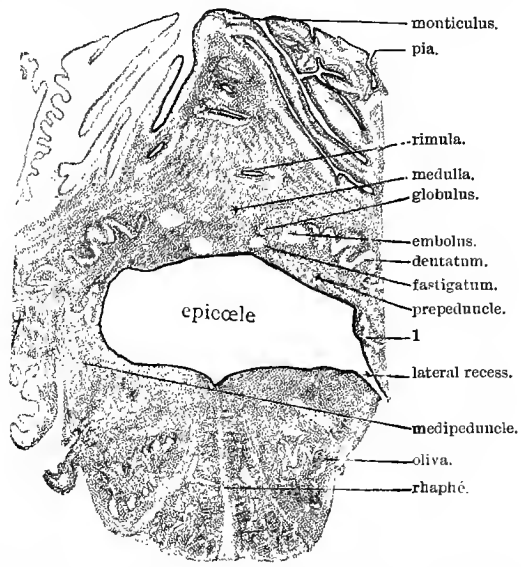

FIG. 58.—Transection of the Cerebellum and Oblongata. From Stilling, Fig. 84; modified somewhat; × 2 —.

Preparation.—The section is stated by Stilling to cut the higher part of the monticulus (see Vol. VIII., Figs. 4716-4719). It evidently passed caudad of the pons and right medipedunele, cutting the left obliquely, the lateral recess being opened on the right. This lack of symmetry is not, perhaps, a serious defect.

§ 38. Points illustrated by Fig. 58.—A. The relative positions of the cinereal masses in the epicœlian roof, as seen in transection; compare the view presented in Fig. 57.

B. The relative positions of the prepedunele and medipedunele; see Vol. VIII., Figs. 4721, 4722.

C. The resemblance of the dentatum of the cerebellum to the corrugated capsule in the oliva, which is sometimes called *dentatum oliræ.*

D. The distinctness of the rhaphé or mesal seam of the oblongata.

§ 39. *Medicommissure* (middle or gray commissure).—According to Wenzel, as stated in Vol. VIII., p. 132, § 113, this secondary junction of the thalami is absent once in six or seven individuals. With five exceptions all of the adult and late fœtal brains in the museum of Cornell University have been either medisected or so prepared as to exhibit the location of the medicommissure; out of the whole number (98) the commissure is absent in only one, a male child at term.

The writer ventures to suggest that some of the reported cases may have been based upon inadequate evidence. Unless the brain is medisected while fresh, or prepared by the injection of a preservative into the arteries or the cavities, or both, the medicommissure commonly fails to be reached; its peculiar softness causes it to break easily; and the imperfect preservation of the adjacent thalamic surfaces might lead to the non-recognition of the slight elevation indicating its existence. If the specimen is allowed to dry slightly, and is then held so that the light is reflected from the smooth endymal surface of the thalamus, then the presence of the remnant of the commissure will be indicated by the absence of such reflection from an area corresponding with its usual location. There is no other part of the brain where an error of observation is more likely to occur.

§ 40. *Conarium.*—The development of this (epiphysis

* Here and in the writer's other articles the occurrence of the termination *re* in words like *metre, fibre, centre*, etc., is in conformity with the rule adopted for the entire work; he regards it as distinctively French; see Vol. VIII., p. 527, § 66, I.

or pineal body) in various vertebrates has been studied by Heckscher of Copenhagen; the literature of the subject is also fully presented by him.

§ 41. *The Paraphysis.*—Under this name (and *Stirnorgan*) Selenka has described (*Biol. Centralblatt*, vol. x., 323–326, 1890) a second mesal appendage of the brain just cephalad of the conarium. It has been observed also by C. Hill. An abstract respecting it is given by Minot ("Embryology," p. 690).

§ 41. The mesal (parietal or conarial) eye has been recently considered at some length by Béraneck, under the title, "Sur le nerf pariétal et la morphologie du troisième œil des vertébrés," *Anat. Anzeiger*, Oct., 1892, 674–689.

§ 42. *The Rhinocœle.*—The persistence of the cavity of the olfactory crus and bulb in other forms than man (and perhaps apes) was mentioned in Vol. VIII., p. 137, § 122. In a paper, "The Partial Occlusion of the Olfactory Lobe in the Canidæ" (*Amer. Monthly Micros. Jour.*,

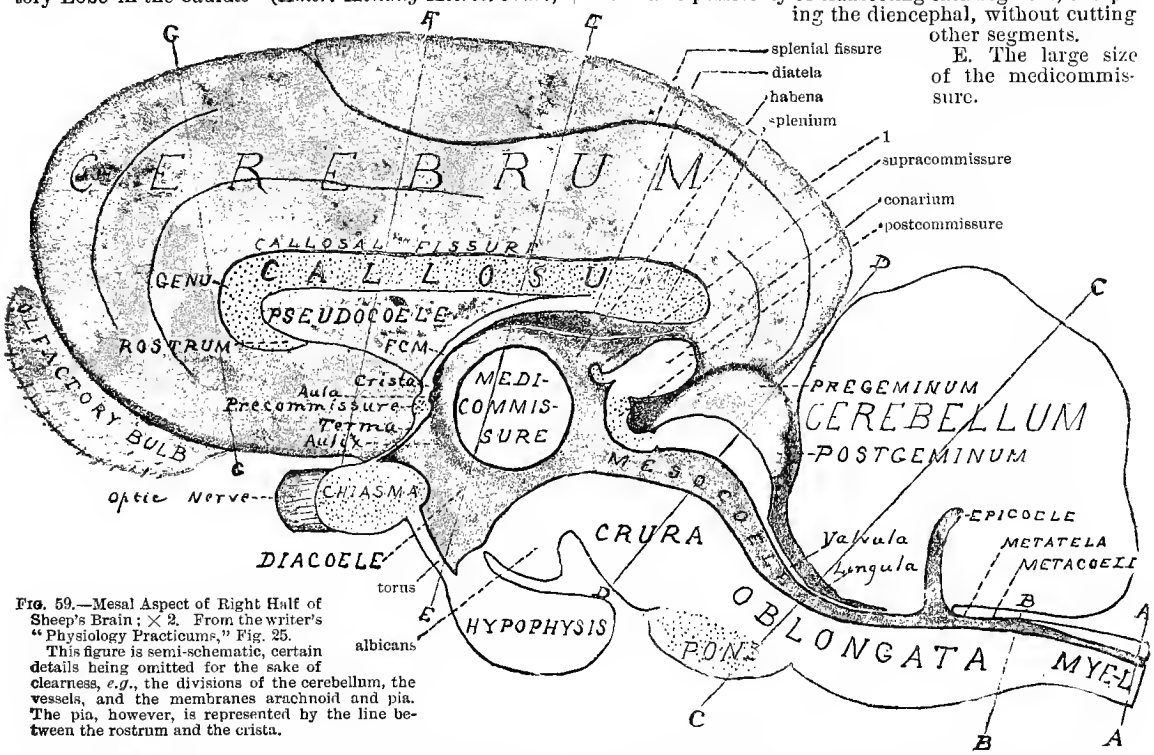

FIG. 59.—Mesal Aspect of Right Half of Sheep's Brain; × 2. From the writer's "Physiology Practicums," Fig. 25.
This figure is semi-schematic, certain details being omitted for the sake of clearness, *e.g.*, the divisions of the cerebellum, the vessels, and the membranes arachnoid and pia. The pia, however, is represented by the line between the rostrum and the crista.

xii., 49–52, March, 1891), P. A. Fish describes and figures cases of partial obliteration of the terminal, expanded portion of the rhinocœle, and complete occlusion of the narrower crural part; so far as his observations go, this is true of all domesticated varieties and of the coyote (*Canis latrans*) and the Australian wild dog, dingo. In view of the attention given to the subject by Broca and Turner (both of whom have based groupings of mammals upon the known or assumed relative development of olfaction and its organ), Mr. Fish's conclusions are here given with some modification:

1. The facts do not warrant Broca's statement as to the existence of a true ventricular axis (core of solid material in place of the primitive cavity) in the olfactory bulb, even in rat-terriers.

2. The bulb is not completely, but partially occluded, or perhaps in process of becoming entirely so.

3. The cavity of the crus, in some wild forms as well as domestic, is completely closed, thereby cutting off all communication between the paracœle and the cavity of the bulb.

4. The acuteness of the sense of smell is not essentially dependent upon the relative size of the rhinocœle.

5. Atrophy is not a necessary concomitant of occlusion.

6. Domestication, and the consequent disuse of olfaction as a means for procuring sustenance, may be a factor in promoting occlusion.

7. In the classifications of Broca and Turner the dog seems to hold an anomalous position, in that he gives every external evidence of macrosmatic power; but by the almost total occlusion of his rhinocœle he approaches structurally the conditions found in the microsmatics. Physiologically he is macrosmatic; morphologically he is microsmatic.

§ 43. Points illustrated by Fig. 59.—A. The general similarity to the corresponding aspect of the human brain as shown in Figs. 4684, 4711, 4718, and 4719.

B. The slighter encephalic flexure.

C. The smaller relative size of the cerebrum, permitting the cerebellum and even the olfactory bulbs to appear in a dorsal view of the organ.

D. The possibility of transecting each segment, excepting the diencephal, without cutting other segments.

E. The large size of the medicommissure.

F. The distinctness of the crista in the adult sheep; Vol. VIII., § 57, N.

G. The non-extension of the callosal rostrum, as a copula, to join the terma, as in man and the chimpanzee, and the consequent closure of the narrow pseudocœle by the pia only.

H. The absence, as in mammals generally, of small foliums upon the lingula; see Fig. 4719.

I. The absence, as in mammals generally, of a metapore (Foramen of Magendie).

J. The completeness of the endymal continuity or cœlian circumscription.

§ 44. *The Fornix.*—This difficult portion of the brain is monographed by Honegger in the *Recueil Suisse* (zoölogie), 1890, v., 311–434.

§ 45. *The Hippocamp.*—Variations in the form of the hippocamp and the collateral eminence are described by Howden in *Journ. Anat. and Physiol.*, xxiii., p. 283, January, 1888. The hippocamp has been treated by Alex. Hill, in a paper of which an abstract is published in the *Royal Society Proceedings*, vol. lii., p. 5.

§ 46. *The Pseudocœle.*—This cavity (the fifth ventricle, or *ventriculus septi pellucidi*) has interesting morphologi-

cal and zoölogical relations; see Vol. VIII., p. 139, § 146, and Figs. 4734, 4735, and 4833.

In the adult cat, sheep, and most other mammals, the two halves of the septum are in contact, and a pseudocœle can hardly be recognized. The rostrum of the callosum also ends in a point, as shown in Fig. 4698 and

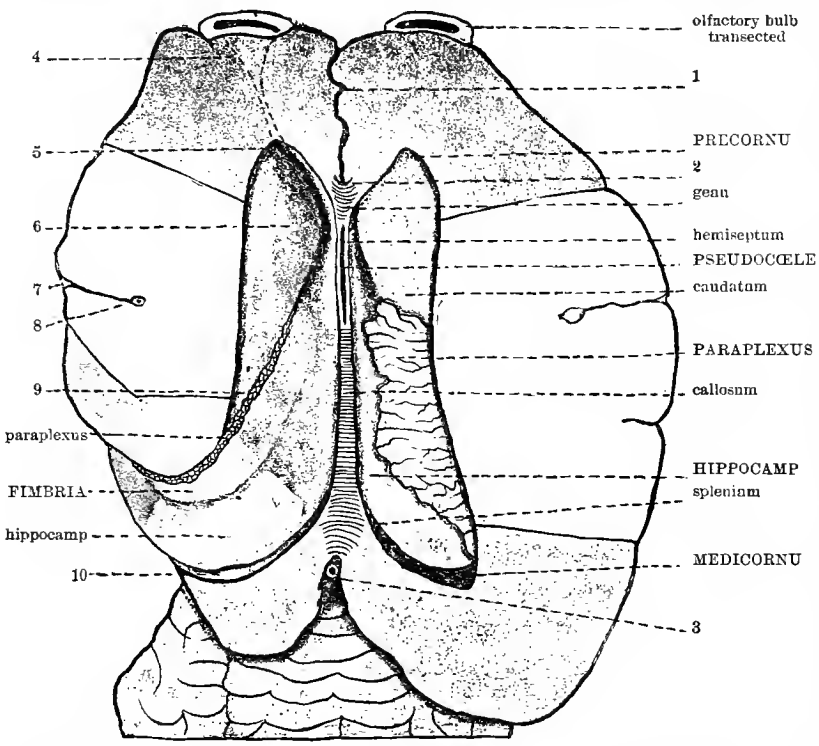

FIG. 60.—Sheep's Brain, the Paracœles (Lateral Ventricles) Exposed; × 2. From the writer's "Physiology Practicums," Fig. 29.

Preparation.—By the removal of successive slices the paracœles have been opened; the left has then been more completely exposed by oblique sections, and the paraplexus trimmed off so as to expose the wide fimbria and the furrow between it and the hippocamp. The plane of section did not coincide exactly with the callosum; the caudal three-fifths of this is represented by the transverse lines; also the cephalic end, the genu; but an intermediate portion is wholly removed, exposing the narrow pseudocœle ("fifth ventricle") and its thin lateral walls, hemiseptums.

Defects.—The cerebral cortex is not represented. The caudal half of the cerebellum is omitted.

1, Intercerebral fissure; 2, callosal fissure; 3, vessel; 4, interrupted lines indicating the continuation of the paracœle into the rhinocœle; 5, precornu; 6, caput of the caudatum; 7, Sylvian fissure crossed by arachnoid; 8, vessel at bottom of fissure; 9, cauda of caudatum; 10, part of caudal wall of paracœle.

this volume, Fig. 59. In man and in a chimpanzee brain prepared by the writer (No. 265 in the Museum of Cornell University) the rostrum continues caudo-ventrad to join the terma, and the pseudocœle is therefore completely circumscribed.

The earlier conditions in man are less well ascertained; strictly their consideration does not lie within the scope of this article, but something must be said in qualification of the account given in Vol. VIII.

According to Marchand ("Ueber die Entwickelung des Balkens im menschlichen Gehirn," *Archiv. für Mikr. Anat.*, xxxvii., pp. 298–334), the pseudocœle arises as an indentation or mesal cleft in the proton* of the callosum-fornix; by the extension of the parts this becomes longer and triangular; its sides, the halves of the septum, become *practically* portions of the mesal walls of the respective hemicerebrums, but if his account is correct they cannot be said (as in Vol. VIII., p. 139, § 145) to be *primarily* such. The complete closure cephalad is accomplished by the ventro-caudad extension of the copula so as to reach the terma at about the fifth month. Probably more remains to be done upon this region.

§ 47. *The Indusium.*—This term (coupled with the adjective *griseum*), is given by Obersteiner (p. 82) to the thin layer of cinerea upon the dorsal surface of the callosum. The presence of this continuation of the cortex upon the callosum was first noted by Giacomini (*Giornale d. r. Accad. Med. Torino*, 1883), and has since been confirmed by Blumenau (*Arch. f. Mikros. Anat.*, xxxvii., 1–15).

The indusium is not represented by Reichert, and seems not to have attracted the attention of Dalton, although some of the beautiful photographs of his transections present faint indications of it. The writer feels compelled to record, with some chagrin, that, upon a series of transections of an adult brain (1824) hardened in a mixture of ammonium dichromate and alcohol, the continuity of the cinerea upon the callosum was recognized in October, 1880; notwithstanding its significance, further examination and publication were deferred.

The ridges and lines known as *striæ mediales et laterales* are interpreted by Blumenau as associated with thickenings of the indusium. It is probable that there is considerable variation in the thickness of the layer, and that it may not always be complete at the meson.

§ 48. *Incallosal Brains.*—A case of total absence of the callosum and fornix is described and figured with un-

* This neuter noun is employed to designate the primitive, undifferentiated mass or rudiment of a part, thus in the sense of *Anlage* of the German embryologists (as adopted by Minot and others), and of *fundament*, as proposed by Mark ("Comparative Embryology"). It avoids certain obvious objections to those terms as English words, and is in harmony with the following phrases from Aristotle, kindly quoted by Professor B. I. Wheeler: τὸ πρῶτον; ἡ πρώτη ὕλη; ἡ πρώτη αἰτία.

(Fig. 61.)—1. Cut surface, extending meso-ventro-cephalad; 2, cut surface of the genu, the cephalic curvature of the callosum; part of its natural, pial surface lies just cephalad; the transverse lines on the areas 2 and 9 are introduced merely to indicate the direction of the callosal fibres, not as representations of microscopic structure; 3, point of disappearance of the pia as a result of cutting away part of the lateral convexity of the cerebrum; 4, meeting-place of the two oblique cut surfaces caused by the exposure of the medicornu; 5, point of reappearance of the pia, which was interrupted at 3; 6, is an area just caudad of the left calcarine fissure; 7, the occipital fissure; 8, the occipital eminence (see under *Defects*); 9, oblique cut surface of the splenium, of which a part of the natural surface is shown just caudad; 10, the cut edge of the paratela covering the thalamus; from 10 a line should pass mesad to the narrow area between the two lines.

Defects.—The alcohol had so bleached the cinerea as to render the recognition of its outlines somewhat difficult, so the width of the cortical zone is only approximately accurate, and the "white line of Vicq d'Azyr," shown in Fig. 4746, is not indicated.

The absence of shading upon the larger part of the surface would imply that it is all upon one level; really, however, the highest part corresponds nearly with the length of the exposed portion of the right caudatum, and from that level there are gentle slopes cephalad, caudad, and laterad. The cut edges of the hemiseptums are also at a lower level than the adjacent lateral parietes. Not all of the arteries are represented. The occipital eminence (8) is indistinct upon the right and made too small upon the left. The cut edge of the paratela (10) is made too thick and the relations of parts are indistinct: see § 55.

On the left, near the word *fimbria*, is a defective patch of shading due to a blemish in the paper.

The arachnoid is represented distinct from the pia at only two places, *viz.*, on the right, near the cephalic end, where the former crosses the wide mouth of a fissure, while the latter dips into it as a fold, and at the callosal fissures, just caudad of the splenium.

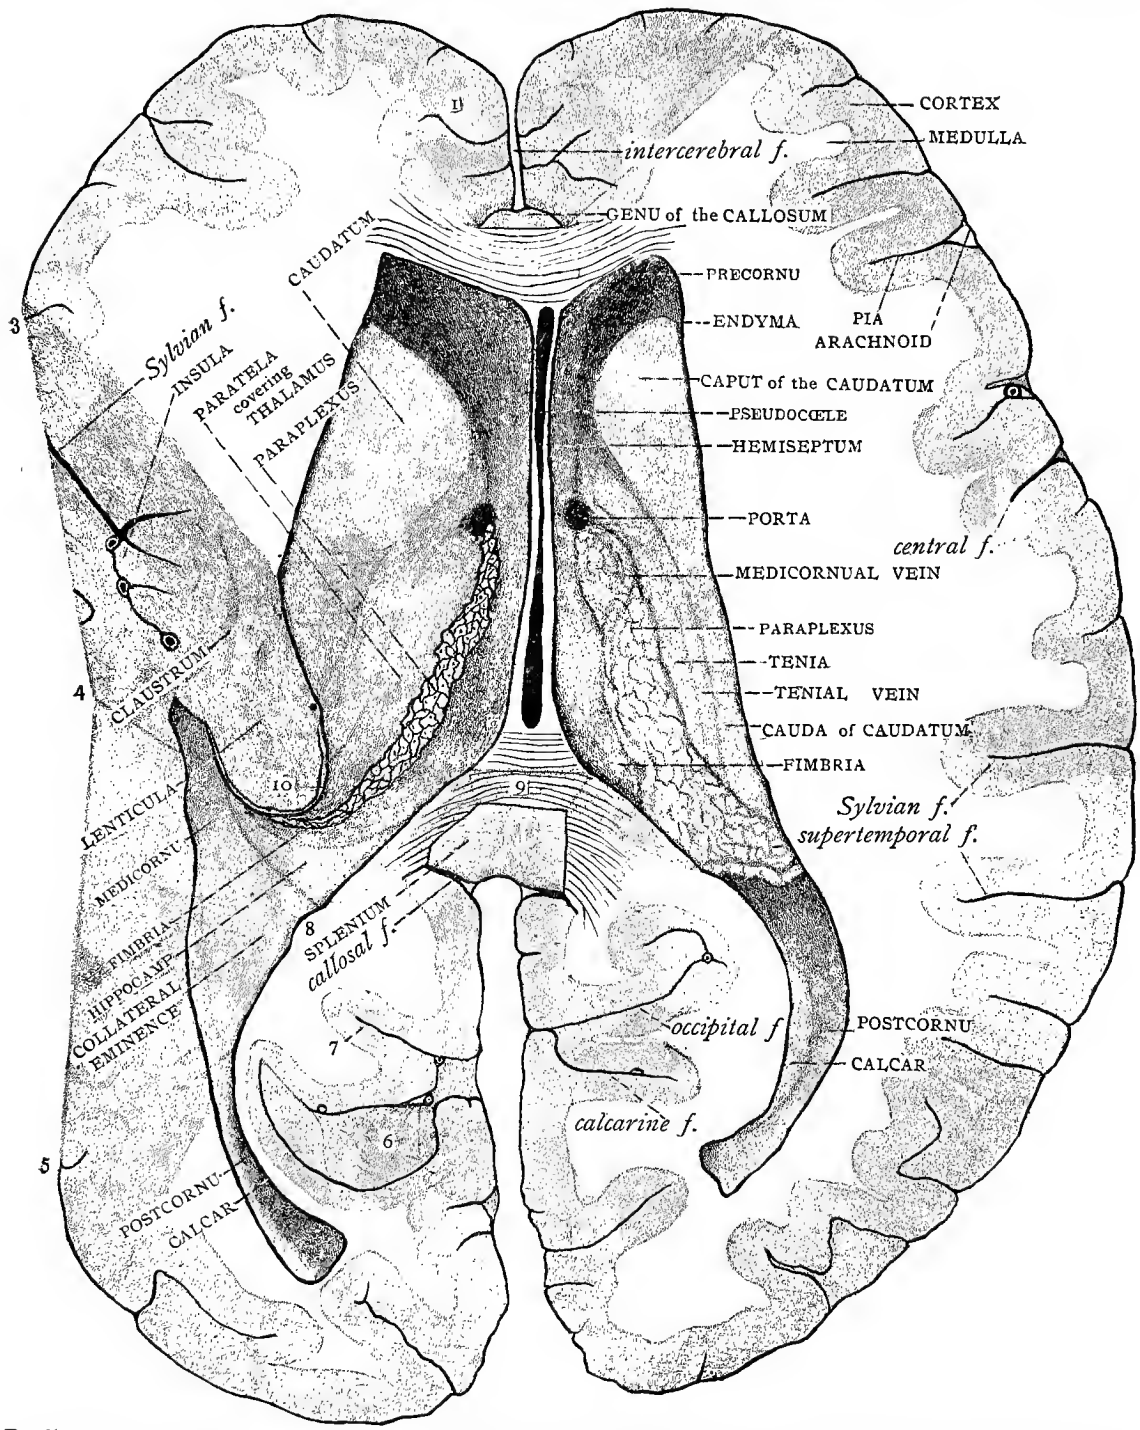

FIG. 61.—The Paracœles (Lateral Ventricles) of an Adult Male, Exposed from the Dorsal Side. Specimen 2867, Museum of Cornell University ; × 1.2.
Preparation.—The entire body (an emaciated consumptive, weighing only 37.71 kilogrammes, 83.25 lbs.) was alinjected through the femoral artery. Eight and one-half litres were introduced on the first day, and some escaped from the mouth. On the second day, and again on the fourth, another litre was injected. On the fifth day there was injected a litre of Pansch-Gage starch mixture (see article Methods, etc., in this volume, § 24). When the brain was removed, on the eighth day, the only odor was of the alcohol. The substance had already hardened somewhat and the arteries were well filled, notwithstanding some of the mass had extravasated into the thorax. The brain was transected through the mesencephal (see Methods, § 25, E), and the paracœles exposed by removing the dorsal portion of the cerebrum in thick slices down to the level of the callosum ; then in thinner slices and wedge-shaped pieces till the desired condition was reached. On the left the medicornu was exposed into the part extending cephalad ; the terminal portion extending also mesad could not be shown without cutting away an undesirably large mass. It is indicated in Figs. 4703 and 4707, although inadequately. On the left also the occipital lobe was cut to a slightly lower level than on the right ; hence, on the right appears the dorsal slope of the calcar, while on the left the plane of section coincides with the line of its greatest elevation, and the width of the posteornu is correspondingly reduced. To lessen the width of the figure a part of the lateral convexity was removed by dorso-ventral incisions between 3 and 4, and 4 and 5, so the line representing the pia ceases at 3 and 5. Finally, the left paraplexus was trimmed off quite closely. (For the rest of this explanation, see at bottom of page 104.)

usual fulness by Alex. Bruce in *Brain*, xiii., 171–190. There are included abstracts of previous cases and reduced copies of the illustrations of some.

In Vol. VIII., p. 192, the writer figured and briefly described one of three incallosal cat brains in the Museum of Cornell University. At the Boston meeting of the Association of American Anatomists, December 29, 1890, he showed the brain of a sheep lacking the callosum and fornix; but this specimen, fortunately unmutilated and thoroughly hardened, has not yet been figured or described.

§ 49. *The Relations of the Thalamus to the Paracœle.*—With the cat, dog, sheep, and all other animals examined by the writer, excepting the apes, the rima ("great transverse fissure") is just wide enough to admit the intrusion of the paraplexus, and there is no sign whatever of the entrance of the thalamus into the composition of the paracœlian floor.

§ 50. Points illustrated upon Fig. 60.—A. The close contact and even interdigitation of the mesal aspects of the frontal lobes concomitantly with the absence of a falx.

B. The width of the fimbria and hippocamp, and thence of the entire fornix, as compared with the human.

C. The apparent absence of the tenia.

D. The total exclusion of the thalamus, even in appearance, from the paracœlian floor.

§ 51. The same condition exists in man during the earlier half of gestation; Vol. VIII., Fig. 4749.

§ 52. In a chimpanzee and orang examined by the writer (Nos. 265 and 2548 in the Museum of Cornell University) the rima is widened, especially in the middle of its length, so that a narrow zone of the thalamus may be recognized, covered, however, by the paracœlian endyma; see the writer's paper, "The Relation of the Thalamus to the Paracœle, especially in the Apes" (*Association American Anatomists, Record*, 1889, p. 20).

§ 53. In the human adult, apparently concomitantly with the thickening of the subjacent thalamus, the two margins are forced apart, as seen in Fig. 4751. But this does not produce a rupture in the floor. The endyma yields or grows correspondingly, and forms a thin portion of the floor, resting upon the thalamus and adapting itself to its contour. Sometimes, as in Fig. 4749, the endyma maintains its independence and constitutes a separable paratela; in other cases the pia primitively covering the dorsum of the thalamus disappears, and the paracœlian endyma becomes so intimately united with the thalamus as to seem to belong to it. Finally, as brains are commonly removed, preserved, handled, and dissected, there is almost sure to occur a rupture along some line between the tenia and the fimbria, so that the thalamus actually appears within the paracœle as represented in most figures—*e.g.*, Fig. 4746. This subject is somewhat fully considered in the writer's paper, "The Relation of the Thalamus to the Paracœle" (*Jour. Nerv. and Mental Disease*, July, 1889, pp. 436–443), where the term *paratela* was first employed.

§ 54. Points illustrated on Fig. 61.—A. The general relation of the paracœles (lateral ventricles) to the cerebrum; although relatively much smaller than in the fœtus, they are absolutely extensive; here their natural extent has been maintained by the injection of alcohol; when examined in a fresh brain or in one hardened in the usual way their walls are often found nearly in contact.

B. The terminal dilatation and squareness of the postcornu, as contrasted with the pointed form which usually exists in brains not prepared by filling the cavities; sometimes, indeed, there has been doubt as to the extent of the postcornu, as admitted by Huxley, "Zoöl. Soc. Proceedings," 1861, p. 250; in Krause's "Handbuch," Fig. 479, the postcornua are merely linea.

C. The great thickness of most of the parietes as compared with their thinness in the fœtus, Fig. 4708.

D. The retention of the fœtal tenuity of a portion of the mesal wall, *viz.*, the hemiseptum (halves of the septum lucidum); see, however, § 46.

E. The considerable length and width of the human pseudocœle (fifth ventricle); so far as the writer has observed it is wider than in any other animal; in Fig. 60 (of the sheep) it is unnaturally wide.

F. The relation of the cortex (cerebral ectocinerea) to the medulla (alba), as an ectal layer following the fissural indentations.

G. The relation of the insula to the Sylvian fissure; the former is a typical subgyre, the latter is a typical superfissure; VIII., p. 160, §§ 260, 261.

H. The relation of the claustrum to the insular cortex ectad and the lenticula entad; see also Fig. 4785.

I. The constitution of the caudatum by two regions, a larger cephalic, the caput, and the cauda, narrow, and following the curve of the medicornu.

J. The junction of the occipital and calcarine fissures so as to constitute as it were a single bifurcate fissure; VIII., Fig. 4768, and this article, § 76.

K. The size and distinctness of the collateral eminence, an ental elevation or colliculus, corresponding to the collateral fissure upon the ventro-mesal aspect of the cerebrum; VIII., Fig. 4768, 4770.

L. The existence, on the left, of an elevation, the occipital eminence, corresponding with the occipital fissure. This colliculus is distinct in the fœtus (Figs. 4748 and 4764), and in some adults (Fig. 4736), is better marked than in this specimen.

M. The location of the portas (foramina of Monro), and their visibility in a direct dorsal view of the paracœles; by reference to Vol. VIII., Figs. 4740, 4744, it will be seen that each porta opens into the corresponding paracœle obliquely, looking laterad, cephalad, and also dorsad; hence it is visible from three different directions at right angles with one another.

N. The distance between the two portas. Deducting the slight length of the passages themselves, this distance represents the width of the aula, the mesal division of the prosocœle, which is commonly reckoned as merely the cephalic part of the "third ventricle."

O. The continuity of the hemiseptum, a part of the mesal wall of the paracœle, with the fimbria, a part of its floor; indeed, their topographical relations may be illustrated by bending a sheet of paper or metal, and holding it so that one portion is vertical and the other nearly horizontal; the former will represent the hemiseptum, the latter the fimbria.

P. The narrowness of the human fornix as measured by the distance between the lateral margins of the two fimbrias in their horizontal portions; compare the sheep, Fig. 60. It is true the word *fornix* does not occur on the figure; but, as somewhat fully discussed in VIII., p. 138, the fornix is constituted by the two hippocamps, with their fimbrias, united at the meson by the fornicommissure (Fig. 4751); in this dissection the fornicommissure is invisible, being upon a lower plane, so the fornix, as a whole, cannot be indicated.

Q. The smallness of the paraplexus as compared with its fœtal condition, Fig. 62 and Vol. VIII., Fig. 4708.

R. The formation of the free margin of the paraplexus by the medicornual vein, considerable in size and more or less contorted, by which the blood of the plexus is returned to the velar vein.

S. The considerable width of the attached portion of the paraplexus. This appears on the left side where the plexus has been trimmed quite closely. The rima is the line of apparent interruption of the parietes for the intrusion of the paraplexus, and is unusually wide in this specimen.

T. The completeness of endymal continuity and cœlian circumscription. These terms are discussed in Vol. VIII., pp. 122, 123, as exemplified upon the mesal aspect of the brain, Fig. 4711. There only the mesal cavities are visible. In the present figure (aside from the pseudocœle, which is not a true member of the series) there appear only the great lateral cavities of the prosencephal. The continuity of the endyma is represented by the uninterrupted heavy line surrounding either paracœle. Likewise is the endyma a continuous sheet upon the sides and floor of this cavity. At the margins of the rima it may be traced as a smooth surface upon the intruded paraplexus, and its cut edges are represented on

the left in this figure. The writer is aware that several authors claim or admit the existence of orifices along the medicornu whereby the cœliolymph may escape therefrom into the adjacent subarachnoid space; but he feels compelled, at present, to regard these as artifacts, like the half-dozen ruptures of the endyma near the porta in the preparation shown in Fig. 4742.

U. The *apparent* entrance of the thalamus into the composition of the floor of the paracœle. This condition is presented on the left side; on the right it is hidden by the overlapping paraplexus.

§ 55. *In what Sense does the Thalamus form Part of the Floor of the Paracœle (Lateral Ventricle)?*—So wide-spread and so deeply-rooted seems to be the notion that the thalamus constitutes a part of the paracœlian floor in the same sense as do the caudatum and the hippocamp, that, much as he would prefer to avoid criticism, the writer is induced to comment upon the current representations of this region.

Admitting, for the sake of occupying common ground, that a certain area of the dorsal surface of the human thalamus is covered by endyma; that it is continuous with the caudatum, and that therefore, like that body, it enters into the composition of the paracœlian floor; none will deny that an adjoining area of this same dorsal surface is as distinctly covered by pia; that it is continuous with the optic lobes (gemina), and like them wholly excluded from the encephalic cavity.

To represent the entire dorsal aspect of the thalamus as a smooth, unbroken surface is practically to affirm one of two things: either the whole is pial or ectocœlian, which would be in contravention of universal belief; or else the whole is endymal or entocœlian, which would involve not only the gemina but the cerebellum and oblongata, a manifest *reductio ad absurdum*.

This, nevertheless, with perhaps a single partial exception, is what we find in the accepted treatises on Human Anatomy, new as well as old.* The figures purporting to represent the natural surfaces fail to exhibit any lines of demarcation between entocœlian and ectocœlian areas either by a difference in texture or by raised edges to indicate where the reflected endyma had been divided. The extreme limits of misrepresentation are reached in Huguenin (Fig. 49), where the utter absence of distinction between surfaces which are said to be inside, and other surfaces which are said to be outside can hardly fail to mislead or at least confuse the reader who is not already thoroughly grounded in correct notions as to the general morphology of the brain.

The prevailing misconceptions as to the relations of the thalamus to the encephalic cavities are exemplified even in the recent translations of Edinger (Figs. 49 and 55) and of Obersteiner (Figs. 18 and 26). In the last, it is true, there is a semblance of demarcation between the diacœlian and paracœlian surfaces of the thalamus, a long, narrow line, just laterad of the "sulcus choroideus;" but in reality that line of reflection of the paracœlian endyma is as shown in Vol. VIII., Fig. 4751, at a considerable distance from the line of reflection of the diacœlian endyma upon the velum.

Dalton's "Topographical Anatomy of the Brain" was designed primarily to aid in recognizing the location of pathological conditions; furthermore, it is evident that the mode of removal of the brain, of handling and cutting it, would not conduce to the maintenance of membranous attachments. But in examining Series C, Plates VIII., IX., and X., for example, it is disappointing to find not only the rupture of these attachments, but also in the outline duplicates an unbroken continuity of line from the diacœle into the paracœle at either side.

With Gegenbaur's "Anatomie des Menschen," 3d ed., 1888, the case is different. This is an anatomical treatise, by a morphological leader. Yet the transections on p. 846 and the dorsal aspects on pp. 824 and 834 utterly fail to comport with the now universally admitted view of the restriction of communication between the diacœle and the paracœles to the portas (foramina of Monro).

§ 56. *The Transitory Cerebral Fissures.*—In the *Jour. of Anat. and Physiol.*, xxiv., 342, D. J. Cunningham makes the following important observation bearing upon the always interesting problem of the distinction between the ordinary mammals and the monkeys, apes, and man:

"Although I have looked for the transitory fissures in cat and dog embryos of different stages I have never seen any infolding of the cerebral wall that could be compared with those we have described in the human brain; the temporary fissures are in all probability peculiar to the primates."

§ 57. Points illustrated by Fig. 62. A. The great size

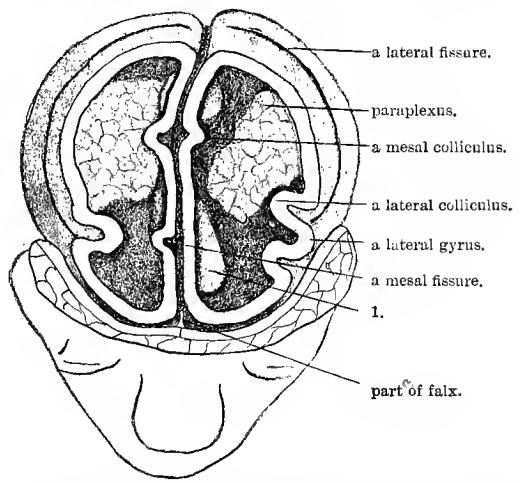

FIG. 62.—Transitory Fissures of a Fœtus measuring 5-6 ctms. from Vertex to Nates, and estimated at Fourteen Weeks; 2770; × 2.2.
Preparation.—After the exposure of the brain the frontal end of the cerebrum was sliced off so as just to clear the large paraplexuses. Of the falx all was removed excepting the fragment shown. The head was tilted so that the face is much foreshortened.

of the paracœles and paraplexuses at this stage; compare Fig. 4708.

B. The slight and nearly uniform thickness of the parietes.

C. Suggestion of a wrinkling or corrugation of the parietes as if from growth within a confined space.

D. The approximately symmetrical distribution of these corrugations.

E. The length of the fissure on either side, reaching from the Sylvian fossa nearly to the meson.

F. The absence of any indication of branching; see § 58.

§ 58. *Do the Lateral Transitory Fissures Branch?*—In none of the specimens or figures accessible to the writer do the transitory fissures on the lateral aspect present the bifurcations which are so common with most of the permanent fissures; it is to be remembered also that in the adult the total fissures (calcarine, occipital, hippocampal) are less subject to branching. The question should be carefully considered.

§ 59. In Vol. VIII., p. 148, § 188, it was stated that the writer had not yet encountered a fœtal brain in which (as said by Mihalkovics and repeated by Osborn, Vol. I., p. 640) the temporary fissures had vanished before the permanent ones appeared, leaving the surface smooth. He has since prepared a specimen (No. 2644 in the Museum of Cornell University) which measures 10 ctm. from the vertex to the nates, and 14 ctm. including the legs, somewhat flexed; the age was supposed to be about four months. Excepting the Sylvian fossa, the lateral aspect of the exposed left hemicerebrum is perfectly smooth;

* The exception referred to is Meynert's Psychiatry, where Fig. 16 includes a line marked L, crossing the thalamus, and more distinct upon the left than upon the right; upon the explanation it is named "Linea aspera," but there is no further reference to it, and its morphological significance is not mentioned: consequently, although it probably does represent a torn edge of endyma, the figure alone would not convey any definite information. It is just to add that the volume of the tenth edition of "Quain" containing the nervous system is not yet accessible.

the mesal surfaces and the right hemicerebrum have not been exposed.

§ 60. *The Permanent Fissures.*—D. J. Cunningham is preparing an elaborate account of the cerebral surface, to be published by the Royal Irish Academy as "Cunningham Memoir,"* No. vii.

In Vols. xxiv. and xxv. of the *Jour. of Anat. and Physiol.* have appeared abstracts (sometimes illustrated) of his views respecting the following: The Intraparietal (parietal and paroccipital of the writer); the Complete Fissures (the writer's transitory and permanent total); the Rolandic (central) Fissure; the Sylvian; the Insular.

The undeniably great value of these abstracts and of the work which they anticipate is somewhat impaired by a tendency toward pœcilonymy (see Vol. VIII., p. 528, § 72), *i.e.*, the employment of more than one name for the same part in the same paper (*e.g.*, "Fissure of Rolando" and "Rolandic sulcus"), and by an ignorance or neglect of American fissural literature.

mainly in the following respects: (*a*) more secondary and tertiary fissures are included; (*b*) the principal fissures are more or less sinuous as in actual brains; (*c*) a long arched fissure, practically identical with Turner's intraparietal (Ecker's interparietal), is interpreted as consisting of three portions, (1) a cephalic, retrocentralis inferior; (2) an intermediate, intraparietal; (3) an occipitalis anterior, for which is given the synonym *Affenspalte.* This, however, is certainly not the writer's exoccipital, but the transverse occipital of Ecker, which the writer has shown to be the caudal part of the paroccipital, which Eberstaller does not separate from the intraparietal.

(*d*) A needless and—in the writer's judgment—unwarrauted change of names; *e.g.*, the short fissure cutting the dorsal margin a little cephalad of the central was first described by Lussana as *solco inflesso*, and that was Anglicized by the writer as *inflected fissure;* by Broca it was called *incisure préovalaire*, and by Schwalbe *sulcus paracentralis;* disregarding priority and brevity, Eberstaller

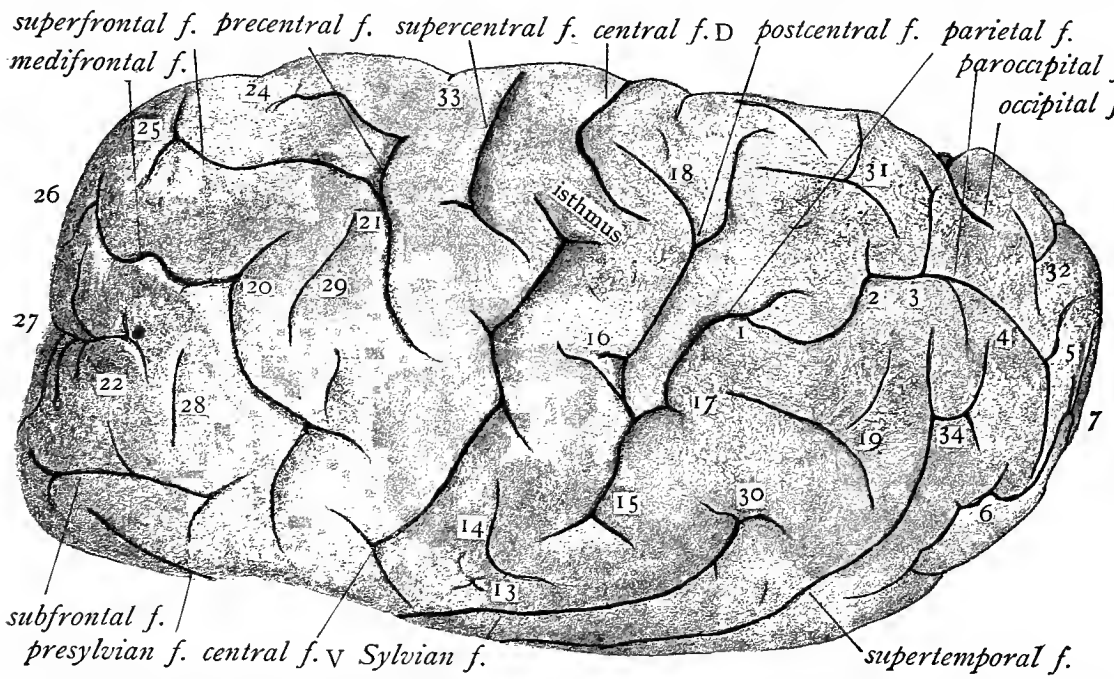

FIG. 63.—The Left Hemicerebrum of a Philosopher (Channcey Wright), from the Dorso-Lateral Aspect; × .9.
Preparation.—See Vol. VIII., Fig. 4779. The figure is based upon a photograph taken as nearly as possible at an angle of 45° with the meson, so as to present the dorso-lateral aspect. The line connecting the superfrontal and medifrontal fissures was made inadvertently.
The nnmerals 1 to 22 are at the same points as in Vol. VIII., Fig. 4779; on that figure 23 is designated the central isthmus, which here has the word printed npon it; 33 is just at the end of the short inflected fissure.

There is also in the *Brit. Med. Jour.*, August 2, 1890, an article by Cunningham discussing general questions connected with the fissures; a brief abstract is given by Hill, *Brain*, xiii., p. 552.

§ 61. Eberstaller has published an admirable account of the fissures and gyres, especially of the frontal region, under the title, "Das Stirnhirn; ein Beitrag zur Anatomie der Oberfläche des Grosshirns," O., pp. 140, with nine figures and one plate. Besides its general excellence two features will especially commend themselves, *viz.*, the Bibliography of 117 books and papers on the subject, and the Lists of Synonyms of each fissure and gyrus. The work concludes with a discussion of the homologies of the human fissures with those of the other primates and the carnivora.

§ 62. Eberstaller's plate presents what he regards as the normal fissural pattern of the lateral aspect only. From the writer's diagram (Vol. VIII., Fig. 4769) it differs

calls it *sulcus præcentralis medialis;* again, the perfect title *subfrontal*, applied by Owen and the writer to the fissure forming the dorsal boundary of Broca's gyrus, has been applied to a fissure or combination of fissures on the mesal aspect.

§ 63. Owen's names, although as a whole the best ever proposed, are in no case ascribed to him, and the considerable section of his "Anatomy of Vertebrates" treating of the fissures and gyres appears to be uuknown to Eberstaller.

§ 64. Even more specialized is the monograph of G. Hervé, "La circonvolution de Broca" [in man and apes], O., pp. 164, with 4 plates, Paris, 1888. The writer is not prepared to discuss Hervé's conclusions as to the degree of representation of the subfrontal gyre in apes; but he is compelled to dissent from the statement (p. 22) that of the two branches of the Sylvian fissure "ascending" and "horizontal" (corresponding respectively to the writer's presylvian and subsylvian) the latter is the more constant.

§ 65. In neither of these papers, nor, indeed, in any

* Since the above was written the writer has learned that the memoir has been published, but he has not yet received it.

others knowu to the writer, does there seem to have been adopted what he regards as an essential requisite to the elucidation of the subfrontal region, *viz.*, the removal of the postoperculum and of other parts in order to expose the depth and relations of the fissures.

§ 66. Points illustrated by Fig. 63 (mostly in addition to those which are enumerated in Vol. VIII., p. 158).—A. The unfamiliar appearance of a hemicerebrum when viewed from this oblique aspect.

B. The distinctness of the angles between the cephalic and the dorsal and ventral outlines; this was commented upon by the first describer of this brain, Professor Thomas Dwight, and appears in Vol. VIII., Fig. 4779, though less markedly.

C. The completeness and width of the isthmus between the dorsal and ventral portions of the central fissure; in Fig. 4779 this is marked 23, but is so much foreshortened as to be hardly visible.

D. The simple, curved form of the dorsal part of the central fissure, with no bifurcation such as exists at both ends of the ventral portion.

E. The independence of the supercentral fissure.

F. The presence of a medifrontal fissure subdividing the large area between the subfrontal and superfrontal fissures.

G. The junction of the postcentral fissure with the parietal, and the continuity of the parietal with the parоccipital; whether this junction occurs at 1 or at 2 cannot be determined at present.

H. The great length of the supertemporal fissure and the complexity of its dorsal end.

I. The absence of a distinct exoccipital fissure.

J. The presence of a long and curved fissure, 6–7, on the lateral aspect of the occipital lobe.

§ 67. *The Homologies of the Central and Cruciate Fissures.*—Upon several grounds, zoölogical, physiological, and even psychological, it is very desirable to ascertain whether the central fissure (f. of Rolando) of man, apes, and monkeys is represented in the Carnivora, and whether the carnivoral cruciate fissure is represented in the Primates.

In Vol. VIII., on pages 115 (§ 32, G, Fig. 4698), 160 (§ 258), and 134 (Fig. 4729) the question is stated and held to be unsettled. It has since been discussed by W. Turner (*Jour. of Anat. and Physiol.*, xxii., pp. 554–581), and by M. Benedikt (*Ibid.*, xxv., p. 213). The latter's views merit high consideration, and although the writer is far from ready to adopt them, they shall be here set forth, with the remark that the lack of figures and a certain vagueness of description render the original somewhat hard to interpret. For the convenience of American readers the publications necessary to cite will be indicated as follows: Broca, "Mémoires sur la cerveau de l'homme," 1888; Meynert, "Psychiatry," translated by Sachs, 1885; Wilder, "Anatomical Technology," 1882, 1886, 1892, and HANDBOOK, 1889.

A. Broca's view that the central fissure is represented in Carnivora by the presylvian of Meynert (superorbital of Wilder) is combated upon the grouud that the latter lies cephalad of the psychomotor areas and the group of giant cells of Betz; "therefore it is proved that the presylvian fissure cannot represent the central fissure; and it is not a consoling spectacle when anatomists, seduced by the error of an eminent man, have so little respect for the results obtained by physiologists and histologists."

B. Benedikt then states that the cruciate fissure lies in the "anterior limit of the psychomotor areas," and concludes that the central is represented by "a transverse fissure on the anterior end of the first primitive fissure in very many non-primate species." This is apparently the *ansate* fissure of Krueg and the writer; in *Anat. Technology*, Pl. I., Fig. 1, it is independent on the right, but on the left connected with the lateral; in the HANDBOOK, Vol. VIII., Fig. 4698, it may be recognized on the right, but is not designated. In this connection it must be noted, however, that Cunningham (*Jour. of Anat. and Physiol.*, xxiv., 153), says "it is now very generally admitted that the *sulcus coronalis* (coronal fissure of Krueg and the writer) has its homologue in the fissure of Rolando."

C. According to Benedikt the carnivoral cruciate fissure is represented in man by two short fissures, *viz.*, (1) "on the inner surface, an arcuate fissure which represents the anterior limit of the paracentral lobe; (2) a little transverse fissure on the outer surface limits generally the superior part of the anterior central gyrus from the anterior part of the frontal lobe, and represents that part of the cruciate which enters in the outer surface in animals."

It is evident that Benedikt's mesal fragment (1) corresponds to the cephalic part of the paracentral fissure, as shown in Figs. 4766 and 4768; but his description leaves one in doubt whether the lateral fragment is the inflected fissure or the supercentral or some third fissure.

It is surely unfortunate that a subject so important should be involved in needless obscurity by the lack of figures or explicit descriptions.

§ 68. In the *Revue scientifique*, vol. xlviii., pp. 555–563, 1892, Topinard discusses "Le type des circonvolutions cérébrales dans la série des mammifères.

§ 69. The cerebral fissures of a child of twelve and one-half years have been studied by Zilgien in the *Jour. de l'Anat. et de la Physiologie*, xvii., 613–621, 1891.

§ 70. Although made primarily for the determination of physiological and psychological correlations, Donaldson's careful "Anatomical Observations on the Brain and Several Sense-Organs of the Blind Deaf-Mute, Laura Bridgman" (*Amer. Jour. of Psychology*, iii. and iv., 1890–91) involved a detailed description of the fissures and gyres and the collation of much literature.

§ 71. In his study of the brain of a murderer (*Amer. Neurol. Assoc. Transactions*, 1892, 54) Donaldson adds to the mass of doubt respecting the validity of Benedikt's claim as to the significance of fissural confluence; see Vol. VIII., p. 163.

§ 72. Several Chinese brains have been described by Benedikt and by Dercum, the latter in the *Jour. Nerv. and Mental Disease*, July, 1889, and September, 1892. An Australian brain is described by A. D. Rolleston in the *Anthropological Institute Journal*, 1887, pp. 32–42.

§ 73. Sir William Turner's address, "The Convolutions of the Brain: a Study in Comparative Anatomy," *Jour. of Anat. and Physiol.*, October, 1890, 105–153, has been referred to in another connection (§ 28).*

§ 74. A case of remarkable fissural malformation and asymmetry is described and figured by W. Turner in the *Jour. Anat. and Physiol.*, xxv., 327–348. The subject was an epileptic, twenty-six years old, and the entire (alcoholic) brain weighed 1,107 grammes (39¾ oz.); the left hemicerebrum 530 grammes, the right 437. The left fissures are stated to have had a normal development and arrangement, but on the right the Sylvian fissure was wide open so as to expose the insula largely; *the central fissure was wholly absent*, together with the precentral and postcentral; the lateral surface presented three arched fissures, demarcating four arched gyres about the Sylviau fissure, a condition analogous to that in the dog and many other Carnivora. The interest and importance attaching to this case, as to the even more extraordinary malformation described by the same anatomist and referred to, with a figure, in Vol. VIII., 193, would have warranted a larger number of better figures, and a representation of the left hemicerebrum.

* Other recent publications on fissures are the following: Lussauer: Circumvolutionum cerebralium, etc., Patavia, 1888, O., pp. 19, 30 plates. Schnopfhagen: Faltungen des Grosshirns, Neurol. Centlbl., vii., p. 549. Benedikt: Beiträge zur Anat. der Gehirnoberfläche, Wien. Med. Jahrb., iii., p. 39, 1888. Eberstaller: Noch einmal die Insula Reilli, Anat. Anz., iii., 13, 1888. Mingazzini, L.: Ueber die Entwickelung der Furchen u. Windungen des menschlichen Gehirns, Unters. zur Naturl. d. Menschen u. d. Thiere, xiii., p. 498, 1888. Mingazzini, G.: Intornoci solchi e le circonvoluzioni cerebrali dei primati e del feto umano, Estratto degli Atti della R. Accad. Med. di Roma, iv., p. 48, 1888. Turner, W.: Comparison of the Convolutions of the Seals and Walrus with those of the Carnivora and of Apes and Man, Jour. Anat. and Physiol., xxii., p. 554, July, 1888. Falcone, C.: Studio sulla circonvoluzione frontale inferiore, Rendiconto dell' Accad. delle scienze, fisiche e matem., Napoli, xxvii., p. 195, 1888. Mahaudeau: Coupes des circonvolutions cérébrales, Bull. de la Soc. d'Anthrop. de Paris, x., p. 771.

§ 75. Four cases of non-union of the occipital and calcarine fissures, in white idiots, have been described by Dercum (*Jour. Nerv. and Mental Disease*, July, 1889). Among all the hemicerebrums prepared by the writer this condition exists in but one, the right of an adult female paretic (Fig. 64). Such cases are instructive on both morphological and zoölogical grounds.

When first formed the two fissures are commonly independent, and in the adult there is often a vadum or shallow at the place of junction. A complete separation, such as is shown in Fig. 64, is a retention of a common fœtal condition.

In most apes and monkeys the two fissures are separate; but usually the calcarine is the longer, and the occipital fails to reach it, a condition comparable with that in the fœtus shown in Vol. VIII., Fig. 4761. In one case, therefore, the interruption is a calcarine isthmus, in the other an occipital isthmus. Cases of occipito-calcarine independence have been observed also by H. C. Chapman (*Acad. Nat. Science Proceedings*, 1892, p. 208) and

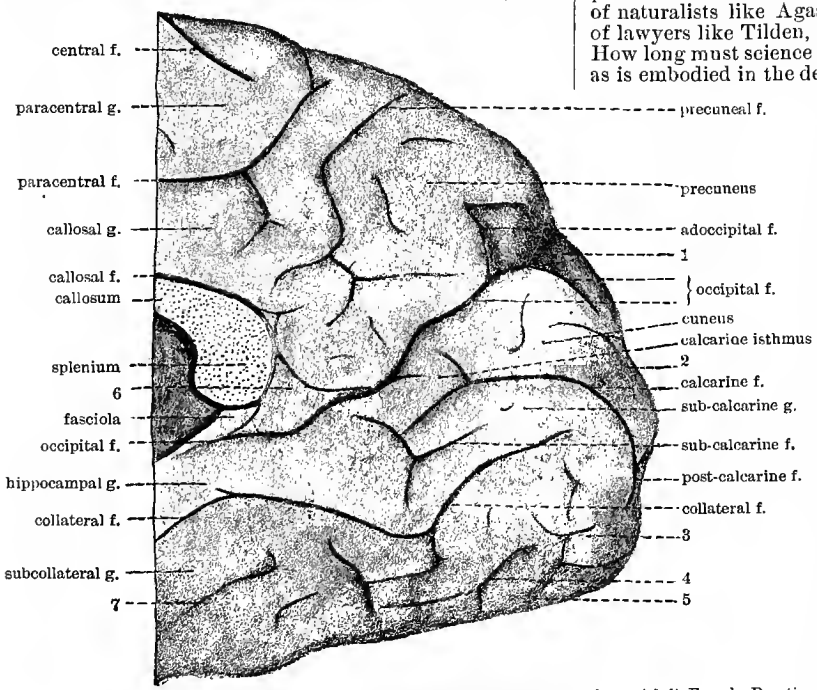

Fig. 64.—Caudal Half of the Mesal Surface of the Right Hemicerebrum of an Adult Female Paretic. No. 2358 in the Museum of Cornell University; × 1.

in the white as well as the negro. The relations of the fissures to each other and to the common stem (called *occalcarine* by the writer, VIII., p. 153, G) have been discussed by D. J. Cunningham, *Jour. Anat. and Physiol.*, xxiv., 327-334.

§ 76. Points illustrated on Fig. 64.—A. The complete separation of the calcarine fissure from the occipital by a calcarine isthmus. On the other side the two are connected as usual.

B. The bifurcation of the calcarine at each end, constituting a zygal fissure; Vol. VIII., Fig. 4773.

C. The extension of the occipital fissure so as to represent what is usually the common stem of it and the calcarine, the occalcarine; Vol. VIII., p. 153, § 213.

D. The presence of a "spur" extending caudad from the occipital toward the calcarine upon the isthmus.

E. The appearance of trifurcation of the dorsal end of the occipital. The middle extension, however, is continuous with the fissure only superficially; the cephalic branch is apparently the writer's adoccipital; the caudal, although doubtless the dorsal part of the occipital, presents an unusual curve and is invisible from the lateral aspect.

F. The extent of the precuneal fissure.

G. The considerable extension of the central upon the mesal aspect; Vol. VIII., p. 157, § 236.

H. The presence of a subcalcarine fissure.

§ 77. *The Need of Particular Brains.*—From the physiological and psychological stand-point it is clearly desirable to study the cerebrums of persons whose mental or physical powers were marked and well known. The present condition of things is illogical and unprofitable. We scrutinize and record the characters and attainments of public men, clergymen, and friends, whose brains are unobtainable. We study the brains of paupers, insane, and criminals, whose characters are unknown or perhaps not worth knowing.

It is at once a reproach and an irreparable loss to science that the community has not yet been convinced that the preservation and study of one's brain is an honor to be coveted. Who can set a limit to the results that might have been attained from the examination of the brains of soldiers like Grant, Sherman, and Sheridan; of preachers like Beecher, Brooks, and Howard Crosby; of naturalists like Agassiz, Gray, and Jeffries Wyman; of lawyers like Tilden, Conkling, and Benjamin Butler? How long must science wait for a general sentiment such as is embodied in the declaration of an eminent historian, that science is as welcome to his brain as to his old hat, and that he wishes he had ten of them?

It is encouraging to know that the brain of the late George Grote, historian of Greece, has been described by John Marshall in the *Jour. of Anat. and Physiol.*, vol. xxvii., pp. 21–68, and that the American Anthropometric Society has already the brains of Joseph Leidy (its first president), of his brother, Dr. Philip Leidy, and Dr. James W. White.*

In Vol. VIII. (§ 280), therefore, the writer urged the preeminent value of the brains of college professors for the elucidation of the correlation between the mind and its bodily organ.

§ 78. *The Greater Need of Average Brains.*—Another aspect of the matter has impressed the writer more and more during the past year, *viz.*, the need of a fissural standard, based upon the careful comparison of large numbers of average, intelligent, educated, and moral individuals, excluding the eminent as well as the immoral, the ignorant and the insane.

The first step in this direction has been taken in the acquisition of the brain of a lawyer embodying all the above-mentioned desirable characteristics. In furtherance, there have been printed numerous copies of the fissural diagrams (Vol. VIII., Figs. 4768 and 4769), with explanations,† for distribution to the classes in Physiology at Cornell University. Besides full explanations, there are the following admission and suggestion:

* In 1890, following the example of the French Société mutuelle d'Autopsie, there was formed in Philadelphia an American Anthropometric Society, in which the writer had the honor of being appointed a member of the Publication Committee. The requirement that all brains should be deposited at the headquarters of the society seemed to the writer from the first undesirable, and he withdrew in the following communication to the president, dated December 20, 1891:

"I hereby resign my membership in the society. Reflection has confirmed the views already expressed to you personally: 1. No other institution or locality is entitled to absorb or appropriate in any sense the encephalic material or reputation, present or future, of this University. 2. My own circumstances and plans for investigation would preclude any such active co-operation as might naturally be expected. With hearty good wishes for the success of the society as a local or university organization for the increase and dissemination of important and accurate knowledge respecting the brain, I remain, etc."

† These diagrams will be sent to any who ask for them.

"As is at present usual in collections, most of the specimens available for study came from ignorant, insane, or criminal persons; it must be borne in mind that the *fissural pattern of the average, intelligent, educated, and moral human being is undetermined.* Hence, although these are believed to be improvements upon previous diagrams, they must be regarded as provisional and imperfect.

"It is hoped that this and succeeding classes may include some who will recognize the desideratum above indicated and will follow the enlightened example of several graduates and professors of this University in giving written directions to the effect that their brains shall be saved for high scientific uses rather than wasted upon worms. Steps have been taken toward the formation of a Cornell Brain Association, and similar organizations might well be established at other institutions of learning and in many cities."

Those who have thus devoted their thinking organ to the service of thought with their successors are present undergraduates of Cornell University, graduates, members of the present teaching body, a former professor and an eminent non-resident lecturer. Perhaps the most interesting results are to be anticipated from the comparison of the brains of a brother and sister.*

§ 79. *Brain Weight.*—In connection with this subject (Vol. VIII., pp. 163, 164) should have been mentioned the paper by Thurnam in the *Jour. of Mental Science*, April, 1866; also Topinard's "Éléments d'Anthropologie Générale." Chaps. xv. and xvi.

§ 80. The relations between the weight of the brain and its parts and the stature and mass of the body, in man are discussed by the late John Marshall, in the *Journal of Anat. and Physiol.*, xxvi., pp. 445–500, with an interest and instructiveness that would have been still greater had he discarded the insular *ounce* and *inch* in favor of the now almost universally used metric measures of weight and length. The following significant conclusion is quoted from Donaldson's review of the paper in the *Jour. of Nerv. and Mental Disease*, xvii., 776, October, 1892: "Dr. Marshall finds that when the smaller weight and stature in the female are given their proper value in calculations, the encephalon in the female is proportionally as heavy as in the male. On this subject, see also an Editorial in the New York *Medical Record*, October 26, 1889.

§ 81. The relative weights of the two halves of the human cerebrum are discussed by W. Branne in the *Arch. f. Anat. u. Physiol., Anat. Abt.*, 1891, pp. 253, 270.

§ 82. A marked exception to the still too confidently affirmed generalization as to the correlation between brain-weight and intellect is afforded by two brains obtained by the writer in 1891; one (2870) was from a lawyer and writer, the other (2912) from an ignorant black janitor. There is little difference in respect to amount of fissuration; when fresh, the lawyer's brain weighed 1225 grammes (43.20 oz.), the janitor's 1250 grammes (44.09 oz.). The janitor was heavy and strong, the lawyer spare, though active; the former under thirty years of age, the latter in his ninetieth year.

§ 83. *Relative Weights of Body and Brain.*—In Vol. VIII., p. 163, § 287, the writer gave as the "least misleading statement," the opinion that the human brain is relatively heavier than that of any animal larger than a cat, in which the cerebrum is fissured.

This must now be qualified. Through the kindness of Director Smith of the Central Park Menagerie, the writer lately examined a male baboon (*Cynocephalus hamadryas (?)*, No. 2980). Its body weighed 5738 grammes (12.6 pounds), and its brain 171 grammes. The body is thus only 33.5 times as heavy as the brain; as stated in Vol. VIII., p. 163, § 286, in healthy human beings the ratio is probably about 1 to 45; in those dying from disease (like the baboon, which died of tuberculosis) it is variously estimated at 35.20, 36.46, and 36.50. Unfortunately the age of this baboon is uncertain; supposed at the Menagerie to be about seven years, the incomplete dentition indicates about two. Other baboons should be examined in this regard. *Burt G. Wilder.*

* They are orphans, and without other near relatives who might object; but it is understood in all cases that objections by husbands, wives, parents, or children shall be respected.

BIBLIOGRAPHY.

In addition to the papers already mentioned in connection with special topics, the following merit enumeration as new treatises or as new editions, or as readily accessible to American readers.

Dana, C. L.: Text-book of Nervous Diseases; being a Compendium for the Use of Students and Practitioners of Medicine. O., illustrated. New York, 1893.

Gray, L. C.: A Treatise on Nervous and Mental Diseases, for Students and Practitioners in Medicine. O., pp. 687, with 168 illustrations. Philadelphia, 1893.

Edinger, L.: Zwölf Vorlesungen über den Bau der Nervösen Centralorgane. Zweite umgearbeitete Auflage. O., with 133 illustrations. Leipzig, 1889.

Edinger, L., Vittum, W. H. (translator), and Riggs, C. E. (editor): Twelve Lectures on the Structure of the Central Nervous System. O., with 133 illustrations. Philadelphia and London. 1890.

Horsley, V.: The Structure and Functions of the Brain and Spinal Cord. O., pp. 223. London, 1892.

Kronthal, P.: Schnitte durch das Centrale Nervensystem des Menschen. Folio, 18 plates. Berlin, 1891.

Minot, C. S.: Human Embryology. Roy. O., pp. 815, 463 figures. New York, 1892.

Obersteiner, A., and Hill, Alex. (translator and annotator): The Anatomy of the Central Nervous Organs in Health and in Disease. O., pp. 432, with 198 illustrations. Philadelphia, 1890.

Quain, J. (Schäfer, E. A., and Thane, G. D., editors): Elements of Anatomy. Tenth ed., in three vols., O. London, 1890-93. (This edition has been largely rewritten, has many new illustrations, and the titles of recent publications.)

Wilder, B. G., and Gage, S. H.: Anatomical Technology as Applied to the Domestic Cat. Third ed., from the second revised. O., pp. 600, 130 figs., and 4 lith. plates. (Chap. X., pp. 400-503, is devoted to the brain.) New York and Chicago, 1892.

The usefulness of the Anatomischer Anzeiger was mentioned in Vol. VIII., p. 164. Special records of neurological literature are made in the Journal of Comp. Neurology by the editor, C. L. Herrick (Granville, O.), and in Schmidt's Jahrbücher für in- und ausländische Medicin, by Edinger under the title of "Bericht über die Leistungen auf dem Gebiete der Anatomie des Central Nervensystems, and by Alex. Hill, in Brain.

BRAIN, METHODS OF REMOVING, PRESERVING, DISSECTING, AND DRAWING. § 1. The article under the above title in Vol. VIII. of the REFERENCE HANDBOOK (pp. 195–201) consisted largely of a series of memoranda often so condensed as to be hardly explicit. The present contribution will be in some degree an expansion of that, with additions and corrections in accordance with what has been published by others and the experience of the Anatomical Department of Cornell University.* It should be borne in mind that these methods are applicable mainly to the preparation and dissection of the brain for purely anatomical or morphological ends, such as are regarded in the articles "Gross Anatomy of the Brain," in Vol. VIII. and in the present volume. For histological and pathological purposes, in addition to the publications referred to in Vol. VIII., p. 196 (first foot-note), consult the works of C. L. Dana and L. C. Gray, named on p. 111 of this volume, and the articles by Dana and Peabody (New York *Medical Record*, January 11, 1890, p. 53) and Van Gieson (*New York Medical Journal*, July 20, 1889, and January and February, 1892); the last, on "Artifacts of the Nervous System," has been reprinted as a pamphlet of 119 pages and 17 plates.

§ 2. *Order of Treatment.*—A. Remarks on the need of more attention to the subject (§ 3); the importance of early recognition of the form and connections of the encephalic cavities (§ 4); preliminary work upon animal brains (§ 5); the utilization of infant and fœtal brains (§ 6).

B. Preservation of fœtal and infant brains (§§ 7–8).

C. Preservative liquids: alcohol (§ 10); chromic acid compounds (§ 11); Fish's liquid, a zinc chloride mixture (§ 12); dry preparations (§ 13); jars (§ 14).

D. Injection methods: entocœlian (§ 15); arterial (§ 16); starch mixture (§ 24).

* Besides the gentlemen named in Vol. VIII., § 2, note, the writer desires to acknowledge the cordial and efficient coöperation of P. A. Fish, B.S., 1890, Instructor in Physiology and Anatomy in Cornell University, and of B. B. Stroud, B.S., '91, Assistant in Chemistry.

E. Removing the brain from infants and late fœtuses (§ 25); from the adult (§ 30); removal in the dura (§ 33); weighing the fresh brain (§ 36); determining its volume (§ 37).

F. Medisecting the cerebrum (§ 25, G); storage of hemicerebrums (§ 38); removing the pia (§ 39); labelling specimens (§ 41).

G. Dissection of the brain (§§ 43–45).

H. Drawing the brain (§§ 46–58).

§ 3. *Need of More Attention to the Subject.*—In the large city schools considerable time is now devoted to the anatomy and physiology of the nervous system, and instruction is given especially in histological methods; but even there the gross anatomy is not always adequately worked out by the student himself upon good material, and it is to be feared that in some medical colleges the conditions described by the writer nine years ago* may still prevail.

Inasmuch as he is permitted to clean scrupulously the abdominal muscles before examining the vastly more important viscera, the average first-year student is at least consistent in deferring the removal of the organ of the mind until he has carefully dissected the muscle that wrinkles the forehead. With saw and chisel he lacerates the brain, tears it in the effort to save entire the sacred skull-cap; injures it yet more in the process of extraction,† and places it upon a hard, flat surface, where its own weight completes the rupture of delicate connections and hopelessly distorts its shape. Here he leaves it (having to boil or clean some bones), perhaps for a day or two, probably drying, and either freezing or decomposing according to the temperature. He then transfers it to a basin or pail, covers it with strong alcohol, notes with satisfaction that the surface hardens rapidly, feels sure of finding out all about the brain, and sees himself a future neurological expert, perhaps even an asylum superintendent. In due time, armed with his "Gray" and a big knife, he succeeds in identifying the cerebellum, the chiasma and the pons. Upon the cerebrum he recognizes the Sylvian fissure, but is doubtful about the central; moreover, the effort to detach the dried-on pia creates so many undescribed depressions and fissural confluences that he imagines, *à la* Benedikt, that it belonged to some hardened criminal. Lifting the occipital lobes, his fingers readily enter cavities which must be the "descending horns of the lateral ventricles," a triumphant refutation of the opinion of certain "theoretical" anatomists that there is no such thing as a "great transverse fissure" till artificially produced. He then slices the brain *secundum professoris artem*, and is so pleased at demonstrating the "*centrum ovale majus*" that he is not seriously disturbed at the presence of an unexpected rent in the callosum and an irregular orifice at either side. Continuing his operations, he finds the interior of the brain a mass of amorphous pulp; suspects that the names in the books have much the same significance as those of the heavenly constellations; modestly admits that he may not be sufficiently advanced to comprehend the brain, and resolves that, when this branch is undertaken again, his *armamentarium* shall consist not of a scalpel but a spoon.

§ 4. *Importance of Early Recognition of the Form and Connections of the Encephalic Cavities.*—In Vol. VIII., p. 196, § 35, the recommendation would be more accurate were the word *details* printed in italics. What the writer desires to inculcate is the desirability of appreciating the fact that the brain has resulted from the unequal thickening of the walls of a series of mesal cavities which were primarily subequal in size, and from the great development of a pair of lateral masses, the hemicerebrums, about the lateral extensions, paracœles, of the mesal series. This idea may be gained from an embryo brain (Vol. VIII., Figs. 4691–4693), from a cast of the adult cavity (Fig. 4703), and from the mesal aspect (Fig. 4711) and cerebral cavity (Fig. 4740), without attempting at first to master the exact contours, much less to learn the names of all the elevations and depressions.

§ 5. *Preliminary Work upon Animal Brains.*—In Vol. VIII., p. 195, § 3, the brain of the domestic cat was recommended. Its advantages are unquestionable in respect to accessibility, ease of removal and preservation, and simplicity of fissural arrangement. The employment of the equally accessible and larger brain of the sheep has been hindered by the difficulty of extracting it from the head with either nippers or saw as commonly employed. This was obviated in the spring of 1890 by P. A. Fish, who devised the following method: The cranium is removed from the rest of the head by sawing on a plane coinciding with the ventral margins of the orbits and of the foramen magnum. The corners of the mass are then sawn off, and the cranium nipped away, beginning with the base.*

In addition to the practical reasons referred to above and in Vol. VIII., the brains of the cat, dog, pig, and sheep present this great advantage over that of man, *viz.*, there is less preponderance of the cerebrum and cerebellum over the other regions and the segmental constitution of the organ is thus more easily recognized. This is stated and illustrated in Vol. VIII., pp. 114–116. In the present volume it is more clearly indicated in Fig. 5, where the dorso-ventral lines, A–E, transect the several segments without involving adjoining segments, although the last requires the section to be made from the ventral side, and all are more or less oblique.†

§ 6. *Utilization of Infant and Fœtal Brains.*—The treatment of this subject in Vol. VIII. (pp. 195, 196, §§ 4, 6, 28, 29, 30) is unsatisfactory, partly from lack of experience since acquired, and partly from excessive condensation. The procedures depend upon the object in view and upon the age and condition of the specimen.

§ 7. *Early Fœtal Brains, Two to Four Months.*—Unless one has acquired considerable skill in manipulating such delicate objects, these should be hardened in place by one of the following methods, or by a combination of them; a five per cent. solution of zinc chloride in alcohol is very effective with embryo brains:

A. Injection of the preservative through the umbilical vein.

B. Immersion; if alcohol, or the above solution, is used the specimen should be suspended in it.

C. Injection of the preservative with a hypodermic syringe both into the body in general and into the cavities of the brain.‡ The cannula should be pushed through the scalp at the margin of the prefontanel, obliquely latero-ventrad so as to traverse the thin parietes and enter the large frontal portion of the paracœle; Fig. 62, Vol. VIII., Figs. 4708, 4709. The success of the injection is shown by the expansion of the opposite half of the head due to the passage of the liquid through the portas into the corresponding paracœle.

The exposure of such brains must be done under or over alcohol; the cranium, and dura must be divided together at each cut. The operation is tedious, but the results are revelations, no matter how often performed; no specimens are more beautiful or instructive; see Figs. 4697, 4756.

§ 8. *Brains of the middle and later gestative periods and at term* are most useful for the comprehension of the early and simple condition of the fissures and of the

* Methods of Studying the Brain: the "Cartwright Lectures" for 1884. *New York Medical Journal*, xxxix., 1884, pp. 141–148, 177–183, 205–209, 233–237, 373–377, 457–461, 513–516, 653–656; xl., 113–116; 64 fig. Abstracts in *New York Medical Record*, xxv., 1884, pp. 141–143, 197–199, 225–227, 365–367, 449, 450, 545, 546.

† The article Anatomy in the last edition of the Encyclopædia Britannica (i., 876) seems to acquiesce in the present state of things as beyond remedy: "In taking the brain out of the cranial cavity this commissure [the medicommissure] is usually more or less torn through, and the cavity [diacœle] is consequently enlarged."

* So expeditious is this method that in 1892 a hardened brain was supplied to each of the one hundred and sixty members of the general class in Physiology for dissection, in addition to the large series of permanent preparations, transections and selected half-brains with good mesal aspects put in their hands for examination. The study of the sheep's brain occupied the class at three exercises of two hours each. The directions form part of the writer's "Physiology Practicums," and he hopes shortly to publish in detail the methods of removal and preservation.

† As to monkey brains see § 8.

‡ So far as the writer is aware, this was first done by Professor S. H. Gage, May 17, 1892, upon specimen 2947.

order of their appearance.* The best results are obtained by their prompt removal as described in §§ 25–29, and hardening in Fish's liquid or other zinc chloride mixture. The arterial injection of such brains rarely preserves them well, and the gyres are commonly so pressed together as to interfere with both the removal of the pia and the recognition of their relations.

§ 9. In Volume VIII., p. 196, § 13, it is suggested that the use to be made of a brain be determined upon in advance. The city neurologist has perhaps only to decide that a brain is needed; but others, like the writer, may find it advantageous to keep in a portfolio (see Vol. VIII., p. 198, § 56) slip memoranda of what he wishes to do with fresh brains, or heads, adult or young, as the case may be; when the opportunity occurs he has only to decide among several things that might be done, and little time is lost.

§ 10. *Preservative Liquids.*—In Volume VIII., p. 196, § 23, a preference was expressed for alcohol. But the brain inevitably flattens in it more or less, and there is difficulty in recognizing the cinerea from the alba.

§ 11. *Potassium Dichromate.*—This is the chief ingredient of the well-known "Müller's liquid," which consists of two parts of it and one of sodium sulphate in one hundred parts of water. Beyond increasing the buoyancy of the liquid, the sodium sulphate seems to have no special value for either microscopic or macroscopic purposes and is often omitted.

Mr. B. B. Stroud has determined for this article that, at the temperature of 20° C. (68° F.), a saturated solution of potassium dichromate contains about ten per cent. of the salt; at boiling the per cent. is forty-four. His method of using it for sheep brains (§§ 5 and 15, notes) was to effect the solution rapidly in boiling water; when cool, enough water was added to float the brain just below the surface.

As soon as the brain is firm to the touch it may be soaked for a day in water and then in alcohol, at first about forty per cent., then stronger, until the alcohol ceases to be colored, after which it may be kept in alcohol of not less than eighty per cent.†

The alcohol that is so colored may be used for the same purpose with other brains, or in the storage of specimens not requiring it to be either colorless or strong.

The Incompatibility of Alcohol with Compounds of Chromic Acid.—A chemist to whom the matter was submitted states that when alcohol and potassium dichromate are mixed in any proportion the salt will be at least partially reduced, and there will also be formed, from the alcohol, various compounds, as acetic acid, acetic aldehyde, etc. These processes will take place in either light or dark, but more rapidly in the light.

§ 12. *Fish's Liquid.*—The following combination was devised in 1892 by Instructor P. A. Fish, of the Anatomical Department of Cornell University, and is found to answer the three requirements of preservation of shape, hardening of substance, and differentiation of tissue:‡ Alcohol (ninety-five per cent.), 200 c.c.; water, 800 c.c.; glycerine, 75 c.c.; zinc chloride, 50 grms. The alcohol and water should be mixed first, so as to get a strength of twenty-two per cent. as determined by the alcoömeter; the variation in commercial alcohol is such as may render it necessary to add more to the mixture, but the total of the twenty-two per cent. mixture should be only about 1,000 c.c. When shaken up thoroughly the specific gravity of the mixture should be about 1.04; if less, a little more glycerine and zinc chloride may be added.

When the brain is introduced it should rest just at the surface, and the vessel should be deep enough to prevent its touching the bottom. If any part projects it may be submerged by covering it with a thin layer of absorbent cotton, the edges of which dip into the liquid. Masses having one flat side, *e.g.*, hemicerebrums, should have that side up, the reverse of the desirable position when—as in alcohol—the specimen sinks to the bottom. If possible the liquid should be injected into the cavities, and into the vessels, and these injections should be repeated daily for a week.

After one to three days the brain will probably sink to the bottom; the pia should then be removed, preferably without taking it from the liquid; it may be steadied with beds of cotton.

Half of the liquid is now to be replaced by ninety-five per cent. alcohol; this is best done by drawing off a part with a syringe and introducing an equal quantity of the alcohol. In the lighter liquid the brain will sink to the bottom, and for two days should rest on the flat side if there is one; if all the surfaces are convex, they should be padded with cotton, and the specimen turned frequently. After two days more half the lighter liquid may be replaced by alcohol, and in two or three days more all of it. The removed liquid may be utilized in various ways; the percentage of zinc chloride is hardly great enough to be corrosive, and the alcoholic strength may be increased by the addition of ninety-five per cent.

§ 13. *Dry Preparations of the Brain.*—Laskowsky's method was mentioned in Vol. VIII., p. 196, § 27, note; the following is translated from the abstract in the *Neurologisches Centralblatt*, vi., 341–342:

A. Rinse the fresh specimen in water to remove blood.

B. Place in a mixture of water, 100 parts; alcohol (ninety-five per cent.), 20 parts; boracic acid, 5 parts; let it remain in a cool place [for at least three days; time not given].

C. Remove the pia.

D. In a saturated solution of zinc chloride in alcohol let the brain remain five or six days; the bottom of the vessel should be covered with cotton.

E. For fifteen to twenty days soak in a mixture of glycerine, 100 parts; alcohol, 20 parts; carbolic acid, 5 parts; boracic acid, 5 parts.

F. Let it dry in the air, protected from dust.

The specimen is claimed to retain its natural volume, distinction of color, and elasticity.*

§ 14. *Preserving-Jars.*—Besides those mentioned in Vol. VIII., p. 199, the following deserve mention from the combination of three desirable qualities—width of mouth, clearness of glass, and cheapness:

A. Tall, round, screw-capped jars, with nickel-plated caps, cork-lined, three sizes, viz.: 4 oz., 8 oz., and 16 oz.; Whitall, Tatum & Co., New York (Fig. 65).

B. Butter-jar, 10 x 20 ctm., with tin screw-cap, lined, capacity about 1 litre; Excelsior Package Co., 49 Warren Street, New York.

C. Landenberger's Specimen Jars.—These have a rubber ring and a glass top retained by a wire. The smaller size is 3 x 3 in., capacity 6 oz. (180 c.c.); the larger, 3 x 4 (high), capacity 10 oz. (300 c.c.) (Fig. 66).

§ 15. *Entocœlian Injection.*—To fill with a hardening and preservative liquid cavities surrounded by flexible walls would seem to be a natural device both for the better preservation of the mass and for the maintenance of the forms and relations of the cavities.†

* The writer desires to reiterate here the conviction expressed in Vol. VIII., p. 149, § 195, and on two previous occasions there named, as to the inutility of the brains of ordinary monkeys and even of apes for the elucidation of human fissural problems; indeed, our present comprehension and nomenclature of cerebral elevations and depressions would be far better than they are had neither Gratiolet nor any other anatomist ever examined a monkey brain.

† The specimens may be more completely decolorized by absolute alcohol (W. C. Krauss), by hydrogen peroxide (Unna, *Arch. für Mikros. Anat.*, xxx., 48, 1887), or by a one per cent. solution of chloral hydrate (Lee, "Microtomist's Vade Mecum").

‡ The microscopical distinction between alba and cinerea is permanent, but immersion in alcohol bleaches the cinerea to nearly the color of the alba in about a fortnight.

* Experiments are now in progress in the anatomical laboratory of Cornell University upon other methods of making dry preparations of the brain. Methods have been described by Stieda (*Neurolog. Centralblatt*, 1892, No. 5), by Moeli (*Centralb. allg. Path. u. path. Anat.*, iii., p. 1, 888), and by Struthers (*Jour. Anat. and Physiol.*, xxii., Appendix, p. ix).

† The method was first employed by the writer, as assistant to the late Professor Louis Agassiz, at Nahant, Mass., in July, 1867, for permanent preparations of great vascular sinuses in rays. Since that time it has been applied in the anatomical laboratory of Cornell University to the preparation and study of hollow organs of all kinds, stomach, cæcum, heart, uterus, kidney, and brain. In 1880 he first learned that the injection of alcohol into hearts was advised in 1860 by Hyrtl, and in 1879 by Mojsisovics; the former ascribes the idea to William Hunter; the writer is not aware that injection of a preservative into the brain cavities was practised or suggested by anyone prior to December 14, 1881, when he employed it upon a child's brain.

The account of entocœlian injection in Vol. VIII., p. 201, § 80, is not only too brief, but requires emendation in the light of later experience.

A. Without conceding the existence of other natural orifices from the paracœles (lateral ventricles) (p. 107, § 54), both human and animal brains present outlets for the

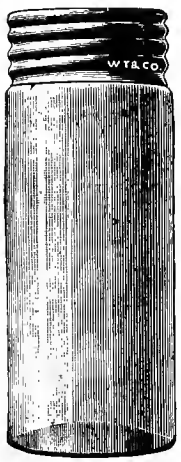

FIG. 65.—Screw-capped jar; see § 14, A.

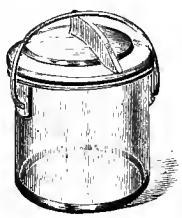

FIG. 66.—Specimen jar; see § 14, C. For sale by H. Landenberger, 25 N. 13th Street, Philadelphia.

escape of the injected liquid so as to obviate the danger of rupturing the thinner parietes under any pressure that might be required for filling the cavities. With animals the myelocœle (central canal of the spinal cord) is pervious through life. With a cat, for example, where 4 ctm. of the myel remained attached to the brain, alcohol injected into the diacœle (third ventricle) with a syringe escaped from the myelocœle in a stream 8 to 10 ctm. long, although the orifice of exit was 42 mm. from the tip of the metacœle and 66 from the place of injection. With human brains (excepting early stages when the myelocœle would probably be sufficiently pervious) there is an ample outlet at the metapore (foramen of Magendie), described under "Meninges;" the same may be the case with apes and some monkeys. Hence the cannula, instead of fitting loosely, may be tied into the infundibulum, or made large enough to fit it closely. In the latter case the cannula may need a rubber collar to prevent its entrance so far as to lacerate the medicommissure or parietes. This precaution may be rendered superfluous by using a cannula which is bent upon itself at a right angle, in the form of a capital letter L, turned one quarter way around thus, ⌐; the shorter arm enters the orifice, the longer rests upon the base of the brain and has attached to it the tube connected with the syringe or injection reservoir. This tube should be short and slender; in the intervals of injecting it may be compressed, or plugged with a glass or cork.*

Entocœlian injection, whether repeated or continuous, may be accomplished from any artificial orifice. The most favorable place is the aqueduct (mesocœle) after transection of the brain (§ 25, E); the cannula may be selected so as to fit it closely; with the cerebellar portion of the brain the metapore would serve as the outlet; with the cerebral it might be necessary to tie the infundibulum to prevent too ready escape therefrom; with a small stream at a slight elevation above the brain it is probable that any excess would be provided for by oozing along the rima. †

A small glass syringe may be employed for injecting preservative liquids into the brain-cavities, either directly or by attaching a rubber tube and cannula.

§ 16. *Arterial Injection of the Preservative.*—This is referred to in Vol. VIII., p. 196, §§ 20 and 68, and is exemplified in Figs. 4684 and 4711. As compared with immersion it has the great advantages of rapidity and thoroughness. Any preservative may be employed, and alcohol may be used at full strength. A low temperature is needless, and even, perhaps, undesirable, as admitted in Vol. VIII., explanation of Fig. 4884.

Barring a slight shrinkage, the natural conditions and relations are maintained.*

It must be admitted, however, that sometimes the gyres are somewhat crowded against each other, so that the pial folds are less readily and safely extracted, and the fissural relations less easily determined.

This is not the occasion for a complete history of injection processes, or for the presentation of claims to originality. The transmission of preservative liquids to the tissues by a constant pressure apparatus connected with the vessels by which blood reached the parts during life is really so simple as well as effectual that it is hard to account for its comparatively infrequent suggestion and adoption. Without previous acquaintance with what had been done by others,† on October 7, 1883, with the co-operation of Professor S. H. Gage, the writer began upon the body of a young chimpanzee (No. 265) an alinjection of the entire body which was prolonged for ten days and was completely successful. In November, 1885, a manatee (No. 844), 150 ctm. long, was prepared in like manner: all the cats (75 to 150 per year) used by the general class in Physiology are alinjected and packed away till wanted; still-born children are commonly so preserved, and the writer recommends that, with alcohol obtained free of tax, all anatomical material in medical dissecting-rooms be thus rendered innocuous, free from unpleasant odor, and fit for prolonged and thorough examination.

§ 17. *Location of the Arteries.*—In Vol. VIII., p. 200, § 68, the relations of the arteries were very briefly referred to; the practical importance of the matter warrants a fuller consideration.

Nearly opposite the hyoid bone, or the cephalic margin of the larynx, each common carotid divides into an ectocarotid ("external") and an entocarotid ("internal"). In the adult they differ little in size, but may be distinguished in that (1) the ectocarotid branches at once and lies farther ventrad, while the entocarotid continues unbranched to the cranium and is accompanied by the vagus nerve.

If the neck was severed close to the head the two arteries may be dealt with independently. If at the level of the chin (as in the head shown in Fig. 4684) the common carotid may be followed up between the muscles, using the tracer rather than the scalpel as much as possible. But if the neck is entire, and especially if it is to be kept so, the ectocarotid may be exposed as for surgical ligation by an incision along the ventral ("anterior") margin of the sterno-mastoid from the lobule of the ear. In any case the ligature must be applied close to the bifurcation of the common carotid or the superior thyroid artery (Fig. 2430) may not be included. As to the vertebral artery, unless there are special reasons for not injuring the vertebræ, the transverse process may be nipped away in order to expose the vessel. The cannula is to be inserted in one, and the other tied after the arteries have been cleared. Since the two arteries unite to form the basilar it makes no difference which has the

* At the writer's suggestion L-shaped cannulas were used last summer in the preparation of sheep brains for the class in Physiology; the preparator, B. B. Stroud, succeeded in making these cannulas very small, and with the point slightly enlarged so as to be more securely tied in the infundibulum.

† For the exposition of the forms and membranous parietes of the encephalic cavities, nothing seems to promise better than the method briefly described under Figs. 4736 and 4751, a combination of arterial injection with injection into the medicornus opened by cutting off the lateral regions of the cranium and brain.

* In this connection, the writer cannot refrain from expressing his regret at the non-application of this and other exact methods of preservation and determination to the brain of Guiteau; see *N. Y. Med. Jour.*, February 23, 1884, p. 206, and *Amer. Jour. of the Med. Sciences*, January, 1883, p. 219.

† Arterial alinjection of the brain is named or implied by Ecker ("Cerebral Convolutions," p. 45), by Mondino (*Trans. Roy. Microsc. Assoc.*, 1885, p. 904), by Foster and Langley ("Pract. Physiology," p. 215), by Key and Retzius ("Studien," i., p. 104), and by the editors of the tenth edition of "Quain," vol. iii., Fig. 88. It was done in 1863 for Marshall upon a Bushman (*Philos. Trans.*, cliv., p. 501); the dates of its performance for Flower and Owen are mislaid.

cannula, excepting that there is some convenience in placing it and the carotid cannula on the same side.

§ 18. *Securing the Cannulas.*—Preferably one cannula is to be inserted in the carotid, whichever is the longer, and another in the vertebral of the same side. Each is to be very securely tied; if there is no shoulder at the cannula point, then tie also around the rubber tubing at its base. All the knots should be the so-called "surgeon's," one end of the thread being passed through twice instead of once; "Anat. Technology," Fig. 41.

§ 19. *Continuous injection* necessitates, in addition to the means of supporting the brain mentioned in § 34, (first) an escape-tube (Fig. 4884) whereby the overflow may pass into the escape-jar, (second) some means of supporting the cannulas and tubes.

The first requirement may be provided for by inserting a metal or glass tube in a hole near the top of a wooden pail, or, with a metal pail, having a tube set at that place; in either case a rubber tube conducts the overflow to the escape-jar. The second end may be attained in either of several ways: The metal pail shown in the figure has soldered to the sides several tubes serving as sockets for flexible wire "cranes;" these wires (of lead, copper, or unannealed brass) may be fixed by wooden wedges if they do not fit securely; with a wooden pail they may be pushed into holes bored vertically into the rim. In either case the wires should be large and the free end beaten out rather thin, so as to be bent easily in the fingers about the tubes connected with the cannulas. Unless the operator has metallic screw-pinch cocks for regulating the flow, so small as not to drag undesirably upon the wire, he may secure the same end by fixing to another wire a wooden spring clothes-pin, by means of which the rubber tube may be compressed.

§ 20. *Turning the Head.*—There are reasons for believing that the position of a head under injection should be changed daily, in order that no one region of the cerebral surface shall be more than twenty-four hours in close contact with the cranial wall.

§ 21. *Repeated Alinjection.*—It is probable that the injection of, say one litre of ninety-five per cent. alcohol, morning, noon, and night, for a week, would harden a brain very well, but accurate experiments on this point have not been made as yet under the writer's observation. If it be tried especial care should be taken to exclude air-bubbles (§ 22), to keep the brain wholly submerged or its base covered with a layer of absorbent cotton dipping into the alcohol. Such injections may be made conveniently with an ordinary rubber-bulb syringe. Repeated injection will conduce to the preservation of the cœlian parietes and of the plexal attachments, but is less effectual than continuous for maintaining the size and form of the cavities.

§ 22. *Exclusion of Air-bubbles During Arterial Injection.*—This is accomplished by letting the alcohol run until no bubbles appear either in the cannula or in a glass tube which is introduced near the can; the can itself should always be at a higher level than the adjoining tube, especially when it is lowered for the introduction of fresh alcohol, since bubbles are then most apt to be formed; on this account the tube should be of ample length.

§ 23. *Filtration.*—Whatever liquid is to be injected into the encephalic vessels must be carefully filtered through filtering-paper, or through absorbent cotton crowded into the pipe of a funnel. This necessity applies to unused alcohol as well as to that which has already passed through tissues.

§ 24. *Starch Injection Mixture.*—Of the mixture first proposed by Pansch, the following modification has been devised by Professor S. H. Gage and the writer:

Dry starch powder	100 c.c.
Chloral hydrate	10 grms.
Water	50 c.c.
Alcohol (ninety-five per cent.)	50 c.c.
Glycerine	25 c.c.
Coloring matter.	

After thoroughly mixing the mass it should be filtered through one or two thicknesses of wet cheese-cloth. To prevent the starch from settling, the cloth should be tilted from side to side or the mass may be stirred during the filtration. If the mass is not freshly prepared for every injection, the stock mass should be filtered occasionally to remove hair or any other object that might clog the cannula.

Among the colors that are available, probably vermilion, red lead, ultramarine, Berlin blue, chrome orange, yellow, or green, are preferable.

§ 25. *Removing the Brain from late Fœtuses, Still-borns, or Young Children.*—This is most conveniently done if the cranium and maxillary region are first cut away from the neck and maudible by cutting with coarse curved scissors from the corners of the mouth to the nape of the neck. The mass thus obtained is compact and may stand upright in liquid.

A. Instruments and materials required. Coarse forceps; coarse, curved scissors for bone; another sharp pair for soft parts; tracer (Fig. 4880); nippers (Fig. 4881); large scalpel; narrow-bladed scalpel, preferably a probe-pointed bistoury;* four vessels, holding about two litres each; two of water; one of preservative; one of saturated brine; if the weight of the brain is to be ascertained (§ 36) the body should be weighed before the head is removed, and there should be provided a fifth vessel of normal salt solution (15 to 2,000).

B. The scalp should be removed completely, together with the ears, and temporal muscles as far as the zygomas.

C. Cranium and dura. In young subjects these adhere closely; hence, contrary to what is recommended with adults, they should be removed together in pieces. With the tracer-point lift the united pericranium (ectal periosteum) and dura near the left margin of the prefontanel, and with the scissors or scalpel slit the tough membrane so as to expose a little of the brain. Grasp the cut edge with the forceps and with the scissors cut out a piece including pericranium, dura, and intervening area of parietal bone. Continue in this way, using the nippers when necessary, until the entire left hemicerebrum is exposed. More and more care will be required to avoid injuring the delicate brain, either by the instruments or the cut edges of bone.

Leaving the falx undisturbed, expose the right hemicerebrum in the same way, but with even more precaution and holding the head so that the left is more or less completely supported in the brine.

D. Falx. Cut the veins that pass from the dorsal margins of the cerebrum to the longitudinal sinus; they are more easily dealt with if the head be slightly tilted toward one side. From Vol. VIII., Figs. 4684 or 4711, recognize that at about the junction of the cephalic and middle third the falx extends only half-way to the callosum. Lift it with the forceps just enough to steady it and cut with the scissors. Draw the cephalic third cephalad and cut off. The caudal two-thirds may be steadied and cut as near as possible to the line of its junction with the tentorium, but must not be pulled upon on account of its connection through the falcial sinus with the velar veins.

E. Transecting the mesencephal. Tilt the head cephalad. Cut the veins that pass to the dura from the sides of the brain and near the caudal end. With the scissors cut the vessels and connective tissue and membranes just caudad of the splenium (Fig. 4711) so as to expose the gemina, the dorsal lobes of the mesencephal corresponding to the crura ventrad (Figs. 4689, 4712, 4783). This is the narrow region connecting the wider cerebellar mass with the still wider cerebral portion, and hence called sometimes the isthmus. With the probe-pointed bistoury or sharp, narrow scalpel cut this just caudad of the conarium; the knife should point almost directly at the tip of the nose if the pons is to be wholly avoided.

* This is practically a longer and stronger syringotome (Fig. 4880), the cutting edge being about 5 ctm. (2 in.) long, ending in a probe point. The curvé is less than that of the syring itome. It replaces the syringotome in the dissection of the entire human brain, and it is particularly applicable to transecting the brain through the mesencephal, to tracing the medicornu and to slitting the pia in following the Sylvian or other deep fissures.

F. Cutting the nerves, etc. The cerebral mass is now held to the base of the skull by the mesal hypophysis (Fig. 4712) and by the paired optic nerves and olfactory crura and bulbs. The slender stalk (infundibulum) of the hypophysis is to be cut first; then the firm fibrous optic nerves. The olfactory crura and bulbs are easily torn, but if care be taken to avoid pulling upon them the latter may be dislodged from their cavities with the blunt point of the bistoury or the tips of the scissors.

G. Medisecting the cerebrum. The cerebrum now floats free, and ordinarily should be medisected at once. Remove the rest of the head to the normal salt solution. Steady the cerebrum by packing absorbent cotton about the base. Divaricate the opposed dorsal parts of the hemicerebrums till the white callosum is visible. Place the edge of the scalpel at the genu and with one sweep, steady and perpendicular, divide the callosum, fornix, precommissure, medicommissure, and conarium; the halves will then fall asunder so that the chiasma and crura may be medisected.*

H. The cerebellum, *etc.*—With the scissors cut the tentorium at its margins. Turn the head so as to expose the cranial nerves and cut them; lastly, with the curved scissors divide the myel as far down as possible. Transfer to the salt solution.

I. Weighing. From the pan of brine, each portion is to be transferred in turn to the salt-solution, and weighed according to the method described in § 36.

§ 26. *Removing the Hemicerebrums Separately.*—The following modification of the method just described has some advantages. After the exposure of the left hemicerebrum cut the veins as before. Let the head tilt to the left so as to expose the callosum. Divide it, as directed above, down to the base of the skull; then the left half of the mesencephal; then the infundibulum and optic nerve; and finally dislodge the olfactory bulb.

These last parts are then to be attended to first on the right side; the falx is easily removed, and the hemicerebrum comes out as soon as the veins are cut. The chief objection to this method is the danger of cutting the mesal aspect of one of the frontal lobes.

§ 27. When there are reasons for not mutilating the head, the removal of a child's brain is much less convenient. The body and legs should be wrapped up so as to be held and turned easily. Unless the child can be held by an assistant, it will be found convenient to let it rest in a sort of trough, like a piece of large roof-gutter; or to roll it up in a sheet of lead, which, upon pressure, will flatten so as to maintain any desired position. The tray or trough must be supported at a level with the rim of the vessel of brine, so that the head may hang over into it when desired. Needle and thread must be provided for sewing up the scalp.

§ 28. *Ventral Exposure.*—For some purposes, *e.g.*, when the organ is to be kept entire, or when the nerve-roots are to be retained, the young brain may advantageously be exposed from the ventral side; this aspect should be first studied, as shown in Figs. 4689 and 4711; then the base of the cranium may be nipped away, or cut with the coarse scissors; it will be well to expose one side completely first, so that any errors detected may be avoided on the other. With care the hypophysis (Figs. 4712 and 4728) may be retained.

This method is less applicable to adult brains, on account of the thickness of the skull; this, however, may be softened by nitric acid; Vol. VIII., § 6, note.

§ 29. On February 1, 1884, the writer removed the cranium of a small monkey (*Midas*, No. 342) by means of a dental engine, working a small saw and a burr. It may be predicted that in time the work now done laboriously with saw and nippers will be accomplished more neatly and expeditiously by some apparatus like the electro-osteotome of Dr. M. J. Roberts, whom the writer is proud to claim as a former student and assistant; see *Virginia Med. Monthly*, March, 1887.

When it is desired to inject the arteries of a subject after the removal of the brain, if the arteries (carotid and vertebral) cannot be tied or caught with *serres-fines*, the regions in which they open may be filled with plaster-of-Paris.

§ 30. *Removing the Adult Brain.*—Portions of the operation are described in Vol. VIII., p. 199.* The writer is confident that whoever once adopts the plan of making a second sagittal section of the calva, one to two centimetres from the meson, will never again attempt to remove the entire calva in the customary fashion.

A. Saw. There is no special advantage of the expensive surgical or anatomical saw over the ordinary carpenter's instrument; it should be thin-bladed, fine-toothed, kept sharp and well-set, and used for no other purpose.

B. Supporting the brain in brine. Although decidedly firmer than in infancy the adult brain should nevertheless be supported in brine during the later stages of its removal; this is particularly essential if the organ is to be removed entire.

The brine should be in an ample vessel, and, if wetting the floor is to be avoided, should stand in a pan or tray. The head is to hang over the end of the operating-table; the vessel of brine is therefore most conveniently placed upon a revolving stool (like a piano-stool) or in a firm chair with some low boxes or thick pieces of board whereby it may be raised or lowered according to the position of the head.

C. The longitudinal sinus should be slit to let out the blood, unless the calval dura is to be removed entire; usually, notwithstanding all precautions, the saw has cut the dura at some point. There—or at any other point—commence with the scissors or probe-pointed bistoury, and cut the dura along the line of the cranial edge first on one side. The head and entire body must now be turned so that the hemicerebrum is supported in the brine. When the dura of the other side is cut the falx may be cut near the cephalic end. In lifting it observe the precautions mentioned in connection with the fœtal brain (§ 25, D). The transection at the mesencephal gives no special difficulty beyond the weight of the cerebrum and the tendency of the head to assume undesirable positions; an assistant is wellnigh indispensable. The extraction of the cerebellum, etc., is practically the same as with the young brain (§ 25, H), and is described in Vol. VIII., p. 199, § 67.

§ 31. *By Removal of the Occipital Region of the Cranium.*—At the meeting of the American Neurological Association, June 22, 1883, as reported in its "Transactions," p. 84, as reprinted from the *Journal of Nervous and Mental Disease*, July, 1883, Dr. Spitzka described as follows a method which, he informs the writer, he has known to be employed by some German anatomists. The writer has not tested this method personally, but is disposed to regard it as better adapted to pathological than to anatomical purposes, and as such entitled to be considered in connection with the usual method, and with that described in Vol. V. of this work, pp. 789–791.

"The scalp is divided in the median line, beginning a little in front of the coronal suture, and extending down the neck. If it is desired to remove the spinal cord the incision is extended to the lumbo-sacral region. Two lateral flaps are formed in the head region, the soft parts being peeled from the dorsal aspect of the cervical vertebræ and the posterior half of the skull. A circular incision is made [with the saw] in the skull, behind the ears, and completely encircling it down to the foramen magnum, care being taken not to injure the connection between the articular processes of the atlas and the occipital condyles: the posterior half of the skull is removed exactly as the calvarium ordinarily is, by taps of a chisel; sometimes a rongeur forceps suffices to complete the division near the foramen magnum. The adhesion about the lateral [and longitudinal] sinus and torcular Hero-

* Contrary to the suggestion in Vol. VIII., p. 196, § 19, it is probable that the best result may be obtained by dividing the callosum first and the chiasma last; if the operation is performed in a long vessel of saturated brine, so that parts do not tear by their own weight, even the tender medicommissure may be cut before it yields.

* See Dr. W. W. Gannett's article in Vol. V., pp. 789–790.

phili can be readily overcome by a home-made apparatus like the knife [spatula, or round-pointed knife, curved flatwise] shown by Professor Wilder. The advantages of this method are: 1, The spinal cord and brain can be demonstrated *in continuo;* 2, the critical operation of lifting the hemispheres and gouging out or injuring the cerebellum in dividing the tentorium is obviated; 3, the nerves and arachnoidal laminæ at the base may be divided without allowing the brain to drag by its own weight. These nerves are divided from behind, forward. As soon as the chiasm is divided, the skull is inclined a little, and the brain allowed to fall into the hands of the operator by its own weight, it being completely separated, except where the olfactory filaments pass through the ethmoid; but these yield readily, and I have gotten the olfactory bulb intact as often by this as the other method. The removal accomplished, the occipital segment is riveted back, and a stick of wood inserted in the spinal canal and extending to the cranial interior restores the strength to the head support, impaired by the breaking up of part of the vertebral attachments."

§ 32. The method of Féré (as briefly described in a paper "Procedé de coupe du crâne," *Soc. Anat. de Paris Bulletin*, ii., 206–207, March, 1877) is by a circular incision very low down from the eyebrows ventrad of the auditory meatus to a point between the foramen magnum and the dorsal arch of the atlas. This, if successful, would uncover the brain very fully and permit its replacement in the calva after extraction; but it seems inevitable that the petrous bones should give trouble as well as be themselves destroyed.

§ 33. *Removal in the Dura.*—Space will not permit detailed directions for removing the brain in the dura; suffice to say that with care and patience and anatomical knowledge it may be accomplished so that only a small part of the dura is absent from the central region of the base. For the safe handling of the brain and for alinjection purposes even the dorsal half of the dura is worth saving.

§ 34. *Supporting the Brain for Injection.*—If the dura has been retained, at three places upon each side, frontal, temporal, and cerebellar (or occipital if the metepencephal has been removed) pin to the dura pieces of broad, stout tape (or strips of cloth 2 to 3 ctm. wide) 10 to 15 ctm. long; in place of pins there may be used garment clasps with serrated edges.

§ 35. For temporary purposes, *e.g.*, examination of the base, preparation for injection, and the single injection of a mass, etc., the brain, supported as directed in Vol. VIII., p. 195, §§ 10 and 11, may be steadied and raised or lowered as required, within any vessel of appropriate size; if of wood, the strips of cloth may be secured by tacks (artists' "thumb tacks" are most convenient); if of glass or metal then an elastic band (*e.g.*, a rubber ring from a jar, or an elastic tape) may be stretched about the rim and the strips passed under it.

§ 36. *Weighing the Fresh Brain.*—One method is described in Vol. VIII., p. 198, § 50. There the brain is added to a pan of liquid already balanced upon the scales. After recording the weight required to balance the added brain, then—having first wet the hands with a liquid identical in composition with that in which the brain is immersed—remove the brain and record the loss of weight. Theoretically it should be the same as had to be added before; practically there is usually some difference, and the average of the two should be taken as representing the true weight.

In employing the first method, some trouble will be avoided if, after the pan of liquid has been counterpoised upon the scales by an approximately equal weight, say 500 or 1,000 or 1,500 grammes, the exact balancing be accomplished by removing or adding liquid with a syringe.

§ 37. *Determining the Volume of a Brain.*—This is done as with any other mass, in either of two ways.

A. Into a vessel of accurately known capacity pour a given volume of liquid; dip the hands in the same, and transfer to it the brain; then, from a graduated vessel add enough more of the liquid to fill the first vessel. The difference between the total capacity of the vessel and the sum of the two volumes of liquid introduced represents the volume of the brain.

B. Set a vessel in a deep pan, dish, or pail. With any liquid (salt-solution, water, or alcohol and water) that is lighter than the brain, fill the vessel just to the brim. Let the brain into it gradually; the overflow will represent its volume.

Obviously a combination of the two methods is most satisfactory.

§ 38. *Storage of Hemicerebrums.*—The human hemicerebrum is a somewhat bulky mass, and may occupy a six by eight inch Whitall & Tatum jar (Vol. VIII., Fig. 4883); sometimes both halves of a cerebrum may be accommodated, although the undivided cerebrum or entire brain commonly requires a nine by eight inch jar.

The most favorable method of storing several hemicerebrums is in jars nine inches in diameter and of any desired height; the specimens are set in tiers of three, their dorsal convexities against the sides of the jar; successive tiers are so placed that a hemicerebrum rests upon the interval between two below. There will be a central vacancy which, if the jar is to be transported, may be filled with absorbent cotton; the alcohol (ninety-five per cent.) should be introduced last.

§ 39. *Removal of the Pia.*—The early removal of the pia* is recommended in Vol. VIII., p. 196, § 33. The writer has seen some otherwise valuable cerebrums materially injured by faulty methods, and offers here a few suggestions.

A. Begin with the central fissure, if it can be recognized, and at about the middle of its length. Apply the coarse forceps so that their approaching points move in the direction of the length of the fissure; pinch up a fold of pia; with the scissors snip at either side of the fold so as to raise it a little; then carry the forceps, held in the same way, more deeply into the fissure, not more than one centimetre deep, and attempt to draw out the intra-fissural fold of pia. If successful, continue to pull *lengthwise of the fissure*, cutting the pia at either side whenever necessary.

Most of the other fissures may be dealt with in the same way; but some, notably the occipital and calcarine, are very deep, and arteries traverse them which must usually be cut more than once.

The Sylvian fissure is not only deep, but spreads laterad over the insula, and there are several arteries. Rather than run the risk of tearing the adjoining gyres it is better to remove only so much pia as easily separates, leaving the rest and the arteries until one of the operculums can be cut off and afterward replaced.

While removing the pia or studying the lateral fissures of young or fœtal brains, breaking is avoided and divarication of the gyres facilitated if the hemicerebrum is placed on its meson on a piece of thick Manila paper (such as is used for the portfolios), which is sufficiently firm to support the organ and yet yields so as to permit the exposure of the fissural depths. When the mesal surface is studied the specimen should rest in a thick bed of cotton.

§ 40. *Prevention of Drying.*—The strong alcohol in which brains are preserved (eighty per cent. and upward) evaporates rapidly while the brain is exposed, as in examination or dissection; it may be dipped in the alcohol occasionally, or—which is preferable with delicate specimens—the alcohol may be allowed to drip gently upon it from a pledget of absorbent cotton. When a specimen only partly submerged in alcohol has to be left for a short time, drying may be prevented by covering it with a thin layer of cotton, one end of which dips into the liquid.

§ 41. *Labelling Specimens.*—Much of the real value of a specimen depends upon its identification as being a certain part of a certain brain, taken from an individual of a certain age, sex, and nationality, and preserved in a certain way. Even if the possessor has so few specimens that he feels sure of remembering the entire history of

* It is understood that this includes the arachnoid, which on most parts of the cerebrum adheres closely to the pia; Vol. VIII., Fig. 4687.

each, his death would abolish the source of information. Hence *every specimen should be labelled in some way.*

In Vol. VIII., p. 198, §§ 55, 56, the method was briefly indicated. Since that volume appeared the writer has observed surprising instances of carelessness in this regard, even upon the part of some who should set an example of scientific accuracy.

Were the specimen never to be removed from the jar in which it alone is kept, the object could be accomplished by inserting the label in the jar or attaching it thereto; but this is rarely an adequate precaution, neither is it often possible to state all the desirable data upon a label attached to the specimen itself. The most satisfactory plan tried by the writer is *the adoption of a serial number for each brain.* This number corresponds to a list or catalogue (Vol. VIII., p. 198, § 56), and is affixed to each brain and to every separated part thereof; that is, the first brain obtained or prepared is numbered 1, and all its parts, when separated, bear the same number, with the addition of letters *a, b, c, etc.*, when there is (which is very seldom) any chance of non-recognition of the nature of a fragment. These numbers may be written with lead pencil (not common ink), and last for some time if not handled; but if written with India ink (ordinary drawing ink, with an equal volume of water), on good paper or parchment, they are permanent. The label may be affixed by one or two small pins.*

For purposes of dissection, photographing, or drawing it may sometimes be necessary to remove the label, but ordinarily it should be affixed to some other region, so that there may be no possibility of misplacement.

§ 42. *Distinctive Labels.*—The ready recognition of brains belonging to groups may be provided for as follows:

A. The sexes are distinguished by using quadrangular labels for males and circular ones for females.

B. Presumed normal white brains have white labels; Africans (of all shades), gray; murderers and other criminals, red; insane and idiots, blue.

§ 43. *Dissection of the Brain.*—As commonly practised this contrasts strongly with the examination of the rest of the body. With the latter, dissection is universal, and sections are seldom made or even studied;† but with the former, sections, macroscopic or microscopic, are the rule, and dissections, careful, prolonged, and thorough, are nearly unknown in medical schools. Like the preponderance of osteology over neurology, the difference is due to the "nature of things;" but like many other natural conditions it may need modification.

The advantages of sections for surgical, pathological, and regional study are obvious; they are easily made, even with the fresh adult human brain, especially by means of the apparatus devised by Professor Dalton.‡ If the human brain were like that of the frog or opossum, with the several segments of approximately equal size, and nearly upon the same plane, the common method would be more appropriate for macroscopic study. But, in view of the extreme cranial flexure and the overlapping of certain segments by others, the objections to sections are as follows:

1. They present plane surfaces which do not naturally exist in the brain.

2. They are almost invariably oblique with respect to the axis.

3. They always include more than one encephalic segment, and are therefore, so far as the beginner is concerned, apt to be more confusing than instructive.

4. They present the parts in contiguity rather than continuity.§

The foregoing objections apply to all sections. A macroscopic section, especially of a brain which has had the cavities alinjected, presents the advantage of exhibiting in perspective enough of the natural contours of parts to facilitate their recognition and comparison.

Admitting, then, that sections have their uses, what is urged is, not that section-making be practised less, but dissection more.

§ 44. *Preliminary Dissection of Alcoholic Brains.*—In the article in Volume VIII., § 34, this is recommended in a single line. The writer is yearly more convinced of its importance on three grounds:

A. The brain is a complex organ and at the best perplexing; the simpler features of form, location, and relation to cavities are morphological, while color, like histological composition, has a physiological significance.

B. The fresh brain is less easy to dissect neatly, and requires constant support against its own weight, whereas the alcoholic may be held in any position and carved like cheese.

C. The beginner should advance cautiously, and therefore slowly, and the medical student is especially liable to interruption. The fresh brain remains fresh but a very short time, while the alcoholic is in itself imperishable. Leisure means not only more careful dissection, but also the taking of notes and the making of drawings; hence all the arguments which the writer has advanced ("Anatomical Technology," pp. 55, 56), in favor of preliminary anatomical work upon a small animal, which may be kept in alcohol for an indefinite time at slight expense, apply to all alcoholic brains in general, and to those of moderate size in particular.

D. After repeated dissection of alcoholic preparations, the anatomist is better qualified to manipulate the fresh brain and to appreciate its beauty. The last word is used advisedly, for, however unattractive may be "subjects" and pathological "cases," the most exacting artistic sense can hardly fail of satisfaction with the soft white and gray and pink of the newly extracted brain. Resting securely in its calva, for him who has been disciplined by prolonged experience with the "pickled" organ, there are few more attractive, stimulating, or nourishing articles of intellectual pabulum than a fresh brain "upon the half shell."

§ 45. *Dissection.*—Whether fresh or hardened, the writer believes the first step should be to slice off the dorsal parts of the cerebrum to near the level of the callosum and the next the exposure of the paracœles as described in connection with Fig. 61; compare Vol. V., p. 790.

The occipital lobes may then be cut off opposite the splenium and one or both medicornus followed to the tip of the temporal lobe.

The next object should be to remove the overlapping parts of the cerebrum from the subjacent diencephal (and so much as may remain of the other segments) so as to obtain a view of the ventral aspect of the splenium and fornix. These may be transected a little caudad of the portas.

There will then appear the velum, with the conarium. If the velum be lifted carefully there will be recognized the attachments along the dorso-mesal curvature of the thalami which are commonly ignored but insisted upon in Vol. VIII., Fig. 4751.

A transection through the portas will give a view of their boundaries, of the cephalic aspect of the medicommissure, and of the caudal surface of the fornix and the precommissure; most of the other features are more easily examined upon the mesal aspect of the medisected brain.

Somewhat full directions for dissection are given by Edinger, in the first part of Lect. III. Complete directions are desirable, accompanied by figures indicating the appearances presented at each stage, such as the writer has framed for the brains of the cat ("Anatomical Technology") and sheep ("Physiology Practicums").

* The ordinary pins are apt to corrode, more or less, and discolor the brain, or tear it when removed. It is to be hoped that pins of aluminium may ere long be available.

† Notwithstanding the example and opportunity offered by works like Braune's "Atlas of Topographical Anatomy" and Dwight's "Frozen Sections of a Child" and "Anatomy of the Head."

‡ Topographical Anatomy of the Brain. Philadelphia. 1885, vol. i., pp. 4–10; abstracts in *N. Y. Med. Record*, February 15, 1879; July 31, 1880.

§ Solly's vigorous reprobation refers particularly to horizontal slicing: "It is unfortunate indeed that candidates for the medical diploma are still very generally required to describe the appearances presented by the brain dissected, or rather destroyed, by the old method of slicing—a method most unphilosophical in its conception, and totally inadequate to impart any real information in regard to the structure of the brain."

§ 46. *Methods of Representing the Brain.**—The following considerations and suggestions† apply more or less directly to all natural history illustrations, but with especial force to the human brain, on account of its softness when fresh, the difficulty of preserving it, the great size of the entire organ, the minuteness of certain portions, the large number of recognizable parts within a small area, the continuity of all, the contiguity of some which are otherwise associated but remotely, the intermixture of two differently colored substances, the complicated relations of the meninges to each other, to the vessels, and to the cavities, and the preponderance of curved and oblique contours over straight lines and planes.

§ 47. *Importance of Orientation.*—With all organs, but especially with the brain, it is essential that the location of the region represented be easily recognized; otherwise details may be unappreciated or even misapprehended. So far as possible, therefore, less familiar parts should be accompanied by such as are unmistakable. It might seem that useless expense was incurred by the publishers of Bourgery and Jacob's magnificent plates in the introduction of faces artistically drawn and colored; but even the expert neurologist is guided in the comprehension of the relative position of brain parts by reference to the apparently superfluous facial outlines.

§ 48. *Enlargement of Complex Regions.*—It often happens that the same section or dissection includes regions that are comparatively simple, and others that are very complex; shown upon a single scale, either the complex parts are unintelligible, or the total is undesirably and needlessly large. Hence, just as the histologist aims first to obtain a general view of all the parts in their gross relations, and then focuses a higher power upon a selected region, so the representer of encephalic structures should give first a view of the whole, if only an outline, and then an enlargement of complex parts to any extent required for their complete elucidation; he can hardly make this enlargement excessive. Compare, *e.g.*, Quain's figures, 258 and 290, and Figs. 4740 and 4742 in Vol. VIII. of this work.

§ 49. Terminal and limiting parts, membranes, and apparently atelic (functionless) parts and conditions should be distinctly shown, or the insufficiency of their representation admitted. "The little things of the brain" might well form the subject of an entire article. From the stand-points of physiology and medical practice such parts as the terma, valvula, crista, conarium, hypophysis, and habena, and such conditions as the reflection of the endyma upon the plexuses, and the dorsal limitation of the porta, are of comparatively slight importance; but their morphological significance is, at least in some cases, inversely to their functional activity, and they cannot be ignored without endangering the success of any attempt to understand or explain the structure of the brain.

Anatomical figures should be something more than pictures conveying a general and vague idea. Where is there an adequate representation of the relation of the diatela to the habenæ, and of the cephalic end of the latter? From the published figures could any student be expected to comprehend the locations and boundaries of the "foramina of Monro" or of "Magendie?" The tenia is easily enough shown as a white band throughout most of its course, but where are its extremities accurately delineated? Anyone can see the caudate prolongation of the striatum, but representations of its termination at the tip of the medicornu are as rare as are figures of the extremity of the filum terminale. Even so considerable a part as the flocculus is seldom figured in such a way as to display either its form or its attachment.

The avoidance of the morphological incongruities and deficiencies which are to be detected in nearly every portrayal of encephalic anatomy demands the admission of three propositions, which are mere truisms in themselves, but radical affirmations when contrasted with their almost universal non-recognition in anatomical works:

1. Every part, organ, membrane,* or surface is either limited or continuous with some other part. If limited, its limits must be defined; if not, its extension must be indicated.

2. Every cavity is either open or closed. If closed, the continuity of its parietes must be demonstrated; if open, its communications must be shown.

3. Every elongated part has a middle and two extremities; not only the former but the latter must be represented.

§ 50. Figures—original ones especially—should be multiplied and descriptions reduced. In descriptive anatomy, whether human or comparative, the text should be subordinate to the illustrations. Some treatises (Charles Bell, Meckel, Milne-Edwards, etc.) seem to have been prepared upon the idea that the description is essential and the figures merely supplementary; on the contrary, words should be employed only when pictures will not suffice—that is, for explanation, commentary, generalization, hypothesis, and manipulative directions.

The arguments for the multiplication of figures may be summarized as follows:

1. A figure is usually a guarantee that something like the object represented has been seen, at least by the artist, and that a certain amount of time has been devoted to its contemplation.

2. The information conveyed by a figure is more real, and likely to be more lasting than that which is expressed in words. In respect to reality and impressiveness, the sources of knowledge may be ranked as follows, in an ascending scale: (1) Description; (2) picture; (3) model; (4) object seen; (5) object handled; (6) object personally prepared. The picture is thus intermediate in value between the thing itself and a description thereof.

3. A figure, if clear and properly placed, is more readily understood than a description, and a saving of time is thus effected. It may be easier for the author to write than to draw, or even than to supervise a drawing, but his personal inconvenience or loss of time should not outweigh the gain to his readers. This applies particularly to dictionaries, cyclopædias, and journals, which are commonly read or consulted in haste. Editors and publishers would find eventual profit in offering to authors the fullest encouragement to employ illustrations so far as possible, and curtail their descriptions in proportion. That it is rather the exception than the rule for such encouragement to be offered is probably due to several causes: *a*, Publishing houses have usually a staff of printers who must be employed, whereas the various processes involved in the making of pictures are commonly done outside at extra expense; *b*, authors too often content themselves with carelessly made copies of "stock figures" instead of insisting upon original representations of objects prepared by themselves. Hence, on the one hand, the exceptionally liberal publisher is liable to get a poor return for any allowance made for drawings, and, on the other, the exceptionally painstaking author is apt to be told that, at best, the engraving will be done if he will furnish the drawings; and, if he cannot draw himself, their cost is likely to deter him from their introduction.† In short, all the existing conditions work to the disadvantage of the reader, who gets but a "pennyworth of [pictorial] bread to a monstrous deal of [verbal] sack."

Before this state of things can be amended the au-

* Every student of any branch of Natural History should compel himself to learn to draw, however slight may be his inherited artistic capacity; not merely the laboratory students in Cornell University, but the members of the large general classes in Physiology and Zoölogy are required to make drawings of entire animals, and of the parts exposed in their dissections.

† The treatment of this subject is based upon the writer's "Cartwright Lecture," III., as reported, with illustrations, in the *N. Y. Medical Journal*, June 14 and August 2, 1884.

* So essential is the exemplification of cœlian circumscription and endymal continuity, that the endyma should be represented by a distinct and rather heavy line, continuous excepting at the metapore; see Vol. VIII., Fig. 4711.

† The liberal provision of the publishers of the REFERENCE HANDBOOK for original illustrations of the writer's articles in Vol. VIII. has been acknowledged therein on p. 107; they have since manifested what might almost be called an unbusiness-like generosity in furnishing the writer with electrotypes of many of the cuts for the use of his students.

thors of books and papers must see clearly the importance of illustration; to paraphrase a witty saying as to the making of an index, the drawings should be made or personally superintended by the author, even if some one else has to write the text.

4. Figures usually occupy less space than descriptions conveying an equal amount of information. This means condensation, convenience, and economy in the present, and a due consideration for our successors in the not far distant future. Exact data are not accessible, but no thoughtful and public-spirited person (unless he be a publisher or printer) can contemplate without concern the logical results of the present rate of book-making activity.

§ 51. Borrowed figures should be fully credited, and all modifications, whether of size or features, explicitly stated. To copy is to compliment, but unacknowledged copying is theft, and unspecified change is misrepresentation.

The ill-effects of omitting to state the source of a figure are two: 1, The originator loses credit to which he is justly entitled; 2, the reader may be seriously misled by the apparent duplication of some really unique feature or the confirmation of an error. For example, in the representations of the meson of the cat's brain by Leuret (Leuret et Gratiolet, Pl. V., Fig. 2), the pseudocœle ("fifth ventricle") is made even more extensive than in man, reaching almost to the splenium. The figure is reproduced, without credit or correction, in Mivart's "The Cat" (Fig. 129). Whoever remarks the coincidence in respect to the pseudocœle, but fails to note that one figure is simply a copy of the other, may naturally infer that the feature in question is normal, or at least not anomalous.

On the other hand, if informed that three of Mivart's figures (125, 126, 129) were copied from Leuret, the student might conclude that the representation of the base of the brain (Fig. 128) was derived from the same source; this would be most injurious to the reputation of Leuret, for the figure in question displays several features (the size and direction of the hypophysis, the disconnected fissure on the temporal lobe, the relations of the pons to the trigeminus and abducens nerves) which it is safe to say never were observed in a feline brain.

Nor is it enough to give the sources of figures in a list, or in the preface, as in Huxley's "Vertebrated Animals;" so great is the labor of preparing an original figure that the acknowledgement of it should be equally as explicit as that of a verbal quotation.

Finally, in the case of modified figures, it needs but a moment's reflection to see that nothing short of an accurate statement of the nature and extent of the alteration can insure full justice to the originator.

§ 52. Drawings should be made as notes. In many cases an outline* drawing, even if hastily made, would convey to the maker, or any one else, at a future time more prompt and complete information than could be embodied in writing covering the same space. But the general employment of sketches, in addition to words, or in place of them, can hardly be looked for until children are taught to draw the intelligible objects about them before they are drilled in the making of the—to them—unmeaning pot-hooks of the alphabet.

§ 53. Figures should be more frequently employed in preliminary or incomplete publication. Probably one of the reasons for the comparative infrequency of pictorial representations of normal, abnormal, and pathological structures, especially in journals, is the difficulty, often the impossibility, of preparing a detailed figure in time for publication. But this need not prevent the early appearance of a figure, if only in outline, illustrating one or more points of greatest importance.

§ 54. Figures should be based upon photographs. Photography enables the anatomist to (*a*) record the appearances of perishable specimens, or of such as are in course of dissection; (*b*) insure the proper perspective; (*c*) save time and labor upon the part of the draughtsman, and thus either reduce the cost of the drawings or render a larger number attainable.

It is seldom that a single anatomical preparation is so perfect as to display all that is needed, and yet present no superfluous parts; often, too, certain points are to be brought out with "diagrammatic clearness," others being subordinated or omitted altogether. Hence, as a rule, the photograph forms rather the basis for the completed figure, and two or more similar preparations may be required for the elucidation of all the desired features.*

§ 55. Figures should be placed so as to be most readily understood and instructively compared. In comparing pictures of two or more houses, ships, or stoves, the architect, shipbuilder, or dealer places them in such positions with regard to one another and his own eyes as may minimize the effort at mental transposition. If asked the principle on which he acts, he will probably say that no principle is needed, that he simply follows nature, experience, and common sense.

With few exceptions it seems to be reserved for those whose business is the contemplation of natural objects, who are credited with more than the average degree of intelligence, and who have at command the recorded experience of centuries, to disregard a matter whose simplicity is equalled only by its importance. In most works there is an utter absence of system. Seldom, indeed, are symmetrical figures placed otherwise than with the meson coinciding with that of the observer, but even this would be less likely to confuse than the apposition of transections of a subcylindrical mass like the myel with the dorsum above in one case and below in another.†

The prevalent carelessness in this regard may be ascribed to three sources: *a*, The still too common idea that illustrations are of secondary importance; *b*, the fact that most figures have been copied and thus placed without regularity, as in the original; *c*, some time and trouble are required to reverse them.

§ 56. *General Rules for the Placing of Figures.*—These rules are based upon a consideration of the whole subject; there is probably no one of them to which exceptions may not exist; but such exceptions should always have a well-defined reason and not occur through inadvertence.

1. Figures should be coadjusted so as to facilitate comparison with each other and with typical structures in normal positions.

2. The dorsal side should be above.

3. Direct views are to be preferred to oblique, though the latter are at times indispensable; *e.g.*, Vol. VIII., Figs. 4740, 4776.

4. Symmetrical figures, or parts thereof, should be so placed that the meson is vertical, *e.g.*, Figs. 4688, 4689, 4698, 4770, 4772.

5. When there is no choice between the right and left sides, the latter should be represented; *e.g.*, Figs. 4767, 4713.

6. Of medisected organs, unless there is special reason for choice, the mesal aspect of the right half is to be shown; *e.g.*, Figs. 4684, 4711.‡

* There is a general and almost unconquerable predilection for shaded drawings. However advantageous shading may be in ordinary art as an element of finished pictures, and when merely a general effect is desired, in anatomical figures correct outlines are essential, and shading should be deferred until the last; otherwise it is too apt to "cover a multitude" of inaccuracies.

* A chief obstacle to the employment of photographs as a basis for figures of brains and embryos has been the difficulty of supporting such delicate objects within range of the camera in its usual horizontal, or nearly horizontal, position. This obstacle is wholly removed by the photographic table devised by Professor Gage and used in the Anatomical Laboratory of Cornell University since 1873. With this the camera may be readily adjusted to any angle, and brought into a vertical position so as to cover an object lying upon cotton, or in alcohol, or even alive in water. The apparatus is described and figured in *Science*, April 11, 1884.

† The common disregard of uniformity in this respect was made the subject of a communication by a medical professor to the Association of American Anatomists at its meeting in December, 1892.

‡ If the fuller discussion of this subject in the *New York Medical Journal*, August 2, 1884, be consulted, the following corrections should be made:

Explanation of Fig. 57, last line, transpose *antimesal* and *symmesal*.
Fig. 59, for *antimesal* read *symmesal*.
Fig. 64, for *symmesal* read *antimesal*.

§ 57. *Designation of Parts upon Figures.*—The full technical names of parts should be given if possible.* From the purely artistic point of view, of course, any extraneous line upon a picture is a disfigurement. But if it be once admitted that the primary object of an anatomical drawing is to convey accurate information, then, unless the shaded figure can be duplicated in an outline (as in Tiedemann, Vicq d'Azyr and Dalton), there should be no sacrifice of the essential to the accessory.

It may be a question whether the names should be upon the parts (as in Gray) or at the sides of the figure, and connected with the parts by lines (Gegenbaur). Upon the whole the latter method seems preferable, especially if the technical names are used.

§ 58. Abbreviations should represent technical terms; they should be uniform throughout the work, and be placed at the sides of the figure.

Four methods of designating parts by abbreviations have been employed: 1, By numbers and unsignificant and ununiform letters, which may or may not be explained in the text (Owen); 2, by unsignificant characters, uniform only in part, and explained at a distance from the figure (Reichert); 3, by uniform and significant, but partly vernacular, abbreviations (Parker); 4, by uniform technical abbreviations ("Anatomical Technology").

The advantages of uniformity in the use of abbreviations are obvious, but it is by no means easy to avoid the charge of ambiguity. Where uniformity is not attempted, care should at least be taken to avoid the use of the same abbreviation for the names of parts which are liable to be taken for one another. For example, in Schwalbe's two representations of the lateral aspect of the crura and adjacent parts (Figs. 280, 281) not only are opposite sides shown for no good reason, with some differences of detail which are puzzling rather than instructive, not only is the pons designated in one by *p* and in the other by *po*, and the tractus opticus by *to* in one and *tr.o* in the other, but the letters *tp* stand for the *tænia pontis* in Fig. 280, and in Fig. 281 for the *tractus pedunculari transversus* [cimbia]. Since these parts are similar in general appearance and direction, and only one appears in each figure, it is doubtful whether any but the most expert anatomist, thoroughly familar with this somewhat obscure region, could escape at least a temporary misapprehension.

§ 59. Abbreviations should be explained in alphabetical order. The "practical" business man would exclaim, "Of course, how else should they be?" An "unscientific" child would adopt the alphabetical order with letters as he would the order of notation with numbers. But the super-scientific writer, especially if he be a German, scruples not to save a few moments of his own time at the expense of others, by giving the verbal equivalents of ten (Huxley, Fig. 19), fifteen (Balfour, ii., Fig. 271), twenty (Quain, Fig. 263), twenty-five (Schwalbe, Fig. 279), or even forty (Meynert [Stricker], Fig. 253) abbreviations, either in no recognizable order at all, or as they occur upon the figure.† The time wasted by each consulter of the figure (not to mention the effect of just indignation) would nearly equal what it would have cost the author to place the abbreviations in alphabetical sequence. *Burt G. Wilder.*

BRAIN, TUMORS OF THE. The article on tumors of the brain published in Vol. I. of the REFERENCE HANDBOOK was completed on the very eve of an important epoch. It was in 1884, and this same year an English surgeon, Mr. Godlee, performed the daring feat of opening the cranial cavity of a man affected with a tumor of the brain, and removing the neoplasm. The patient died at the end of a month; nevertheless he survived the immediate effects of the operation, and was also relieved of the headache, vomiting, and epileptic convulsions which had been the most distressing symptoms of his disease (see Case 1 of table).

Between this date, November 25, 1884, and the present writing, January, 1893, the operation of trephining for brain tumor has been performed eighty-five times. These cases have been arranged in chronological order in the table commencing on next page:*

The intellectual, philosophic, and even romantic interest attaching to the operations for brain tumors much exceeds their actual practical importance. The attempt has been made to estimate this from analysis, not only of the operations which have been performed, but also of the fatal cases of brain tumors on record, not operated, but submitted to post-mortem examination. The latter has shown that a very large proportion would have been inoperable, either because a local diagnosis could not have been made, or because the locality, though diagnosed, was inaccessible; or because the tumors were multiple or malignant; or, finally, because they were too large for extirpation. The last objection can often be met by the observation that an early operation might have proved successful, though by delay the tumor had grown beyond the bounds of surgical possibilities. This observation, however, holds good for tumors in any part of the body.

Tubercular tumors—the most common variety by far in childhood—are frequently multiple, either at the time of operation or by recurrence shortly after; and are then, of course, unfavorable for operation. For extremely malignant tumors (carcinoma) the prognosis is naturally as hopeless when the growth is situated in the brain as when it exists in other organs. On the other hand, sarcomata, when primary, have not unfrequently been removed with success.†

A table quoted by Keen, in the article on "Brain Surgery," in this HANDBOOK, shows the relative proportion of different varieties of brain tumors in a total of five hundred and eighty cases collected by Hale White and Bernhardt. Nearly a quarter of all (twenty-three per cent.) were tubercular, only four per cent. were carcinomatous. In twenty-two per cent of the cases cited the nature of the tumor is not stated.

Hale White estimates that only nine of his one hundred cases could be considered as operable. No tumor, even the most benign, could be considered operable which is situated at the base of the brain, or in the cerebral axis (Starr), which is widely infiltrated, or which, as already noted, is multiple. Out of three hundred brain tumors in children collected by Starr, one-third were in the cerebral axis. Tumors of the cerebellum are fairly accessible, but operations upon them have proved very much more dangerous than operations upon the cerebrum. The space for operation is much narrower; precise localizing symptoms are much less distinct, and frequently fail altogether. On the other hand, the general symptoms are especially severe, owing to the excessive intracranial pressure; and this same condition endangers the operation by causing the brain to bulge through the opening. The close proximity of the affected part to the most vital organs of the cerebro-spinal axis renders shock imminent. The tumor is very frequently tubercular, and finally optic neuritis has nearly always reached an advanced stage before the operation is undertaken, so that when, by exception, the patient has survived the operation, he has remained blind.‡

* This need not preclude using, in place of Latin terms, the paronyms appropriate to the language in which the paper is written: *e.g.*, for *hippocampus*, *hippocamp* (Eng.), *Hippokamp* (Ger.), *hippocampe* (Fr.), or *hippocampo* (Ital.). See Vol. VIII., pp. 530-531.

† Almost equally objectionable is the omission of the original pagination in reprints from periodicals.

* Seventy-two cases were tabulated by Knapp more briefly in his monograph on intracranial tumors in 1890. The table given in the text necessarily includes Knapp's cases, but has been compiled from the original sources, and contains more details than are given by Knapp. Horsley mentioned two more cases, at the International Medical Congress, of which he gives no details. Keen has two more cases, as yet unpublished.

† In the case reported by Weir and Amidon the cerebral symptoms occurred after the patient had already been operated upon for sarcoma of the neck (Annals of Surgery, June, 1887).

‡ The symptom of choked disk, when present, has long been considered more nearly pathognomonic than any other of cerebral tumor. Segnin has, however, recently declared that many cases of enormous tumors do not present choked disk, and, on the other hand, this ocular lesion occurs in persons who have no intracranial disease. "Indeed, in my experience as regards tumors of the hemispheres, the rule is that the optic nerves are normal" (Bost. M. & S. Journal, February 5, 1891).

No. of case.	Operator, date, reference.	Sex and age.	Trauma or not.	Time between trauma and first symptoms or duration.	General symptoms.	Localizing symptoms.	Diagnosis.	Operation.	Situation and nature of tumor.	First result.	Final result.
1.	Bennett and Godlee (*Lancet*, Dec. 20, 1884).	Man, 25 years.	Blow on head.	One year.	Violent headache, diffused, for some months; severe monthly convulsions eighteen months after blow, ceased eighteen months before operation; double optic neuritis (vision normal); vomiting.	Paroxysmal twitching left side face and tongue, first symptom; aura on left side precedes general convulsion, this for two and one-half years; progressive paresis left arm, then twitchings left leg, then slight paresis left side face; paresis arm most marked at shoulder.	Tumor upper third fissure Rolando.	November 25, 1884. At first no tumor found: incision inch long into anterior central convolution.	Glioma, size of walnut, middle upper third right ascending convolution.	Temporary recovery; diminished headache, vomiting, convulsions; paresis increased.	Development hernia cerebri; then septic meningitis; death in one month.
2.	Macewen (*Lancet*, May 16, 1885).	Male, 35 years.	.....	.....	.....	Left hemiparesis; right facial paralysis.	.....	Trephined over right ascending frontal; mass removed.	Tubercular membranous mass.	.....	Recovery.
3.	Sciamanna (*Bull. d. R. Accad. Med. di Roma*, xi., 1885; Quoted by Knapp, "Intra-cranial Growths").	Male, 46 years.	Injury to head in right frontal parietal region.	....	Headache, vomiting, fainting, convulsions; slow pulse, somnolence.	Left hemiplegia; later, right oculo-motor and facial paralysis.	....	Trephined over seat of injury; nothing found.	Glioma right centrum ovale, from right inferior cornu to corpora quadrigemina.	.....	Death in two days.
4.	Hirschfelder and Morse (*Pacific Med. and Surg. Journal*, April, 1886).	Man, 71 years.	None.	.....	Dull, heavy pain, especially over occipital protuberance, vertigo; increased tendon reflexes; optic neuritis both eyes, most on left, failure of vision in last three months; occasional convulsions, vomiting, hiccup; totters on standing with closed eyes.	Jerkings left face, arm; then paresis left arm; drooping left side forehead, corner mouth; left leg stiff and lame; slight anæsthesia left trigeminus.	Tumor middle portion right post. centralis gyrus; pressure on parietal lobe (inferred from anæsthesia); posterior convol. also diagnosed, because face, arm, and leg all involved.	February 15, 1886. Tumor excised, 2½ c.c.	Soft infiltrating glioma middle portion right post. centralis gyrus.	....	Death on eighteenth day of septic encephalitis.
5.	Fraser (*Lancet*, February 27, 1884).	Man, 44 years.	Injury to head.	.....	Headache, vertigo, vomiting, stupidity.	Right hemiplegia, with contracture; indistinct speech, amnesic aphasia, agraphia.	Tumor of left ascending frontal convolution.	Trephined; nothing found.	Glioma left temporal lobe, involving ascending convolutions; second (?) tumor in middle right ascending parietal.	.....	Death.
6.	Durante (*Lancet*, Oct. 1, 1887).	Woman, 35 years.	None.	.....	Impaired memory; severe vomiting: movements uncertain: melancholia, taciturnity.	Anosmia one year: left eye displaced downward.	Tumor anterior lobe; paralysis olfactory nerve.	May, 1884. Dura here perforated by tumor; drainage-tube through opening made into ethmoid; enucleated.	Fibro-sarcoma occupied anterior fossa cranium; weighed 70 grms.	Stitches removed seventh day; drainage-tube fifteenth day.	Patient recovered promptly; still well four years after operation.
7.	Græme Hammond (*Medical News*, April 23, 1887).	Woman, 29 years.	.....	Illness, two and one-half years.	Début in sudden loss consciousness. At time of operation, double choked disk; exaggerated reflexes; four or five epileptic attacks; agonizing headache, anterior, on left side.	Convulsions limited to left side; paralysis left face; gradual paresis, then paralysis left arm; gradual paresis left leg.	Tumor cortical or subcortical at motor centres.	Operation; tumor not found.	Three cysts in a line in motor region of anterior central convolution, right side.	.....	Death in twenty-one hours.
8.	Weir ("Annals of Surgery," St. Louis, 1887, with Amidon).	Woman, 26 years.	Four previous operations for sarcoma, neck.	Two months duration symptoms.	Precipitate micturition and defecation; frontal headache: slight optic neuritis, left side.	Cramps left leg, paresis left knee; cramps and numbness left hand; narrowing left palpebral fissure; paralysis left upper arm; left patellar reflex exaggerated.	Tumor upper extremity Rolandic fissure, one inch from median line.	Trephining; no tumor found.	Sarcomatous tumor from lower surface left lobe cerebellum compressing medulla; originated in pia, extended into spinal canal 10 ctm.; not continuous with cerebellum.	Disappearance of headache and spasms; temporary recovery. Hernia cerebri which increased to size of hen's egg.	Death in ten weeks.

9.	Horsley (*Am. Journal Med. Sciences*, April, 1887).	Male, 20 years.	None.	.....	None described, except frequent headache.	Cramps left thumb and forefinger; clonic opposition twice daily for three months; then epileptic fits, always beginning with same clonic spasms; conjugate deviation head and eyes to left; left lower limb drawn up; paralysis left leg after a fit; reflexes exaggerated in left arm.	Tumor at thumb centre; *i.e.*, junction lower and middle thirds ascending parietal convolution.	Tumor removed with excision of surrounding tissue, June 21, 1886.	Tubercular nodule at junction lower and middle thirds ascending parietal convolution.	Second day, paresis left buccal branch facial; paralysis left arm; fifth day, left hemianæsthesia without analgesia; complete loss muscular sense; persistent exaggeration deep reflexes.	Complete recovery from epilepsy and paralysis.
10.	Horsley (*Brit. M. d. Jour.*, April 23, 1887).	Male, 38 years.	None.	... .	Epileptic convulsions; semi-comatose for ten days before operation.	Convulsions began in left shoulder, followed by left hemiplegia.	Tumor involving upper part of middle third of Rolandic region.	Tumor removed.	Infiltrating glioma, 4½ oz., from shoulder centre as diagnosed.	Return full consciousness; mental state, normal for three and one-half months; diminution paralysis; patient walking in two and one-half months; no fits.	Recurrence tumor in three months. Death in six months.
11.	Ibid.	Male, 37 years.	None.	.....	Constant headache.	Gradually increasing right hemiplegia; fits beginning in right forefinger; slight defect of speech; no fits for three months before operation.	Tumor in left motor cortex, involving hand centre, pressing on Broca's convolution.	Removed December 7, 1886.	Tumor, 4½ oz.; situated as diagnosed.	.....	No more headaches or convulsions; hemiplegia not cured, but progressed no further.
12.	Ibid.	Male, 18 years.	None.	.....	Headache, vomiting; optic neuritis; increasing weakness all limbs; epileptoid attacks; one year in bed.	Left arm and leg especially weak; in fit conjugate deviation head and eyes to right.	Tumor in right lobe of cerebellum.	Removed December 17, 1886.	Tubercular tumor; 7 drachms, as diagnosed.	Died in nineteen hours from shock; chronic general tuberculosis of viscera.	
13	Bennett May (*Lancet*, April 16, 1887).	Male, 7 years.	.....	.....	Frontal headache; vomiting; amblyopia; optic neuritis; nystagmus; abolition knee-jerks.	Gait reeling backward and to left.	Cerebellar tumor.	Removal tumor.	Tubercle size of pigeon's egg.	Shock.	Death.
14.	Suckling (*Lancet*, October 1, 1887).	Girl, 12 years.	.....	....	Headache, vomiting; dimness vision two years; diplopia for two weeks; vertigo; double optic neuritis; nystagmus; diminished knee-jerks.	For nine months right hemiparesis; paresis both external recti; dilated left pupil; intentional tremor right arm; staggering, tendency to fall forward; mouth to left; left conjunctival reflex lost; paralysis left eyelid; diminished faradaic contractility for all left side face.	Tumor left lobe cerebellum, growing down, compressing left facial and both sixth pair nerves.	Curved incision, convexity downward to base of left mastoid process; two trephine openings on line from occipital protuberance to tip of mastoid; cerebellum bulged; tumor inaccessible.	At post-mortem tumor found occupying all left lobe and much of middle lobe.	Shock.	Death in forty-eight hours.
15.	Birdsall and Weir (*Phil. Med. News*, 1887).	Male, 42 years.	None.	.....	Since 1885 vomiting; moderate headache; drowsiness; begioning neuro-retinitis; diplopia, transitory.	Unsteadiness gait; numbness right leg, hand, and shoulder; left lateral hemianopsia.	Tumor on mesial aspect right occipital lobe, involving primarily the cuneus, and perhaps paracentral lobule; locomotion impaired from pressure on tentorium.	March 9, 1887. Trephining one inch above occipital protuberance, one inch from median line; tumor too large for removal; incised, softened contents removed.	Sarcoma occupied tip of right occipital lobe.	Death from hemorrhage in a few hours.	
16.	Markoe (*Phil. Med. News*, November 5, 1887).	Man, 25 years.	Injury to head.	.....	Convulsions; dull headache.	Depression over left parietal.	....	Operation over depression; cyst removed containing brain substance.	Cyst hemorrhagic.	.....	Recovery.
17.	Macewen (*Lancet*, August 11, 1888).	Girl, 7 years.	No record.	.....	Convulsions.	Pain and spasms in right great toe. Paresis right leg.	.....	Removal tumor.	Tubercle size of hazel-nut from top of left ascending parietal; tubercles in meninges.	....	Recovery.
18.	Ibid.	Male, 22 years.	Injury to head.	... .	....	Paresis right arm; spasm tongue, face platysma.	....	Removal.	Cyst size of filbert removed from base of left ascending frontal.	....	Recovery.

No. of case.	Operator, date, reference.	Sex and age.	Trauma or not.	Time between trauma and first symptoms or duration.	General symptoms	Localizing symptoms.	Diagnosis.	Operation.	Situation and nature of tumor.	First result.	Final result.
19.	Macewen (*Lancet*, August 11, 1888).	Female, 25 years.	Syphilis.	.	....	Left hemiplegia.	..	Trephined over right parietal region; removed degenerated gumma.	Yellow mass over upper part right ascending convolutions.	.....	Recovery.
20.	Lucas Championnière (*Journal de Med. et de Chir.*, lix., 1888).	Male, 29 years.	.....	.....	.....	Right hemiplegia; aphasia.	.....	Trephined over left ascending frontal convolution; removed tumor.	Large hyperostosis.	Recovery: still partly paralyzed.	
21.	Rannie (*Brit. Med. Journal*, May 19, 1888).	Black woman, 35 years.	Syphilis, tertiary.	.....	Intense headache, eighteen months; buzzing in ears, visual hallucinations; gloomy dreams; alternated exaltation and depression; convulsions, June 1, 1887.	Pain and tenderness right frontal and parietal region; in fit left angle mouth retracted; conjugate deviation to left side; left upper extremity adducted: forearm flexed, wrist and fingers flexed; left leg extended stiffly, clonic convulsions left arm and face, then left hemiparesis face and limbs.	.....	Operation June 9, 1888, over right ascending frontal convolution: growth removed with piece of dura and brain-tissue.	Degenerating gumma.	Paresis remained, but steadily diminished; headache and fits ceased.	Recovery.
22.	Von Bergmann ("Surgical Diseases of Brain." Wood's Monographs).	Man, 25 years.	.....	.....	Epileptic attacks; headache; début with sudden apoplexy.	Right hemiplegia and contraction motor aphasia; loss of muscle sense.	Tumor in Rolandic region.	Chiselled piece of skull 7x7¼ ctm.; cyst evacuated, communicating with lateral ventricle.	.....	.....	Death in four weeks from meningitis.
23.	Seguin and Weir (*Am. Jour. Med. Sciences*, 1888).	Male, 39 years.	None.	.. ..	Memory impaired for two years; no optic neuritis; mental action slow but accurate; headache only recently.	Five years before operation spasm drawing right cheek and neck; epileptic attack three years later, preceded by twitching right forearm, hand; eight months before operation paresis right arm; speech thick and slow; paresis lower facial; slight anæsthesia right cheek; numbness over right arm.	Tumor, probably subcortical, in left hemisphere, involving centre for face and partly for arm.	Trephined, removed tumor.	Sarcoma size of large almond within white substance, one inch below posterior edge second frontal and anterior edge precentral gyri; *i.e.*, in fasciculus for face.	Temporary complete hemiplegia; nearly complete aphasia; eight weeks after operation epileptic attack began with twitching right side face; aphasia diminished then increased again.	Six months after operation in perfect health: slight hemiparesis right side; walk normal, knee-jerks normal both sides; sensibility normal: aphasia almost gone.
24.	Keen ("Trans. Am. Surg. Ass'n," vol. vi., 1888).	Male, 26 years.	Injury to head when three years old.	Twenty years.	General neuralgic pains, 1884: violent epilepsy twice weekly, 1885; severe pain in head; pulse 60°, irregular; anorexia; insomnia; two years before operation temporary blindness, first in right eye, then left; moderate headache; optic neuritis.	Painful scar on left side head; paralysis right arm, then right leg, then right face; right pupil dilated, insensitive; vision right eye imperfect; marked aphasia; in fit, right hand closes tightly, first finger, then thumb; right deviates upward and outward; paresis right internus right eye, and of left inferior and superior recti; paresis inferior fibres orbicularis on both sides; vision right eye much reduced: left, homonymous hemianopsia; clonic convulsions, chiefly in right limbs; slight paresis right hand.	Tumor pressing on anterior lobe, left hemisphere, involving third frontal convolution; fibroma. Operation December 15, 1887. Incision through tender scar; enucleated tumor from fossa behind squamous bone.	Fibroma presented at opening; extended from base third frontal convolution backward 2½ inches to fissure Rolando, upward into external part, first frontal internally to corpus striatum; weighed 3 oz.; measured 7¼ in. in circumference.	First week, increased aphasia; large clot found in wound; then disintegrated; then aphasia diminished. Second week, temperature, 104° F.; hernia; diarrhœa; abundant discharge cerebro-spinal fluid; temperature normal by third week.	.....	Recovery eighty-fourth day; mind clearer; paralysis gone; one epileptic attack in five weeks.

25.	Wille (*Allgem. Wiener M.d. Zeitung*. December 18, 1888).	Woman, 43 years.	. . . . .	. . . . .	Dementia; difficult deglutition; incontinence urine and fæces; disturbance speech; later, convulsions.	Swelling over left parietal bone. After incision, paresis right leg, right facial, right mon.	Tumor parietal lobe.	First operation, incised swelling; no pus; later necrosis bone trephined; subdural pus evacuated; no tumor found.	Tumor, size pigeon egg, in front part left paracentral lobule, extending into upper part ascending parietal convolution; second smaller tumor in middle of ascending parietal convolution, both gliomata.	Death.	
26.	Fitzgerald ("Sajous's Annuaire," Vol. II., 1888, p. 36).	Girl, 16 years.	....	.....	Convulsions.	Amaurosis right eye; partial paralysis (?).	....	Left temple trephined; contents of cyst evacuated.	Echinococcus.	.....	Recovery.
27.	Heath and Ross (*Lancet*, April 7, 1888).	Male, 20 years.	.. ..	....	Headache; optic neuritis.	Left hemispasm; left hemiparesis; tenderness of lower right ascending frontal.	....	Trephined over tender spot; large adherent growth found; could not be removed.	....	Relief of headache.	Recovery.
28.	Macewen (*Br. Med. Journal*, August 11, 1888).	Female.	... .	.. ..	Headache; dulness.	Orbital growth; nodule on skull half way between ascending frontal and anterior aspect; spasm right face and arm; myosis left pupil.	.....	Trephined over nodule; tumor durn one-half inch thick removed.	....	Recovery.	Died eight years later of nephritis.
29.	Pean (*Gazette des Hôpitaux*, Febrnary 21, 1889).	Man, 28 years.	.....	... .	Epileptic attacks six years, extremely frequent; temperature, 104° F.; night before operation thirty-seven attacks status epilepticus.	Painful spasm right great toe; stiffness right lower limb; tonic, then clonic convulsions same limb; extension these to arm and face; not always loss of consciousness.	Tumor motor centre right lower extremity.	Operation December 7, 1888. Trephined at upper part left ascending frontal and parietal convolutions; trephine just outside sagittal suture. Enucleated tumor without injury to brain.	Tumor at post. half of opening; grows from dura over left ascending convolutions; fibro-lipoma (Pean); endothelioma (Cornil).	Day after, only six fits.	Two months after operation no more attacks.
30.	Fischer (*Verhandl. d. deutsch Gesell. f. Chirurg.*, 18th Congress; also, "Annals Surgery," St. Louis, 1889).	Male, 37 years.	....	.....	Vertigo, convulsions.	Paresis, then paralysis right arm; diminished sensibility; paresis leg; slight aphasia.	.....	First operation nothing found: second, removed tumor piecemeal.	Sarcoma pressing on left central convolutions.	After first trephining, convulsion, headache ceased; paralysis less; aphasia increased after second operation; also recovery.	Death two months later from recurrence growth in dura.
31.	Pilcher and Dana ("Annals Surgery," St. Louis, 1889).	Man, 33 years.	Thrown from carriage, struck head, in 1882.	One year to first general symptoms	Irritable, childish; apathetic after one year: general convulsions, 1884, then petit mal; severe frontal headache; mental impairment; double optic neuritis; exaggerated reflexes.	In abortive attack, conjugate deviation head and eyes to left; tonic spasm right arm and leg.	....	Operation over seat of injury, angular gyrus; no tumor found.	Glioma in left occipital lobe, extends to tip of left frontal, reaches lateral ventricle, island of Reil softened. Cicatrix had misled.	Death from respiratory failure.	
32.	Wood and Agnew (*Univ. Med. Magazine*, April, 1889).	Man	... .	....	Vertigo, severe headache; loss mental power; optic neuritis; loss equilibrium.	Left hemianopsia.	....	Trephined over right cuneus; found and evacuated hemorrhagic cyst.	Tumor right temporo-sphenoidal lobe.	.....	Death from hemorrhage.
33.	Parker (*Brit. Med. Journal*, Nov. 30, 1889).	Man, 38 years.	.. ..	.....	Long-standing headache; mental dulness.	Total paralysis left arm: paresis left leg; puffy swelling of scalp over right parietal eminence.	.....	Trephining over swelling. Tumor removed with adherent dura. Suppuration on nineteenth day; hernia cerebri reduced by mechanical pressure.	Rounded gummous tumor size walnut under right parietal eminence.	Total hemiplegia one day after first operation. Ten days afterward, second for suppuration. Total loss headache.	Recovery on eighteenth day.
34.	Thomas ("Trans. Amer. Inst. Homeop.," 1889, p. 461).	Woman.	.....	.....	Headache; thick speech; no optic neuritis.	Spasm left hand; loss of consciousness; paresis left leg and face; paralysis and rigidity left arm.	... .	Removed tumor weighing 3 oz.	Middle Rolandic region, pressing on but not involving convolutions.	.....	Death in three days.
35.	Limont and Page (*Brit. Med. Journal*, Oct. 26. 1889).	Woman, 32 years.	Confinement.	Fourteen days.	Sudden unconsciousness; numerous convulsions.	Spasms right arm: speech affected.	.....	Portion large glioma removed (from lower part ascending frontal?)	.....	Temporary recovery.	Growth recurred.

No of case.	Operator, date, reference.	Sex and age.	Trauma or not.	Time between trauma and first symptoms or duration.	General symptoms.	Localizing symptoms.	Diagnosis.	Operation.	Situation and nature of tumor.	First result.	Final result.
36.	Maunsell (*New Zealand Medical Journal*, 1889).	Man, 18 years.	.....	.....	Headache; vertigo; vomiting; reeling gait; blindness; anosmia; convulsions; dilatation pupils; incontinence urine and faeces; head and neck much swollen; eyes prominent; head retracted.	Staggering to right; convulsions begin with retraction head; involve right arm and leg.	....	Trephined over cerebellum; evacuated subtentorial cyst.	Cyst of cerebellum four inches long, two inches broad.	.....	Recovery, but blindness persists.
37.	Verco (Intercolonial Medical Congress, Australasia, 1889).	Boy, 11 years.	Fall from tree.	Eight months.	Pains in head; screaming at night from pain; tired sighing; three convulsions three weeks ago; occasional vomiting; incontinence urine and faeces; tenderness head; dimness vision; pupils dilated; sluggish; double optic neuritis; head very large, 24 inches in circumference.	Left palpebral fissure smaller; paresis left lower facial; hyperæsthesia right front chest; paresis left hand; slight bulging right temporal and anterior parietal region.	Hydatid cyst from size of head, unilateral bulging, and paresis.	Trephined over bulging region, 4½ inches above right meatus, 4½ inches behind angular process, 3½ inches from sagittal suture.	Cyst over area 4x2; adherent to temporo-sphenoidal lobe; central convolutions displaced upward.	Death from meningitis; temperature 104° Fahr.	
38.	Mercanton and Combe (*Revue Méd. de la Suisse*, Aug. 20, 1889).	Girl, 12 years.	Blow by teacher's ruler over nose and forehead.	Fifteen months.	Headache first symptom; diminished vision; in two years atrophy optic disks.	Jacksonian epilepsy right arm; no aura, no loss of consciousness; temporary paralysis arm after attack; later right face, then right leg involved, then aphasia after attacks; intentional tremor; rotation head to right, no deviation eyes, tender point near bregma to right of sagittal suture.	Tumor in middle left ascending frontal convolution, reaching superior third above, inferior third below, also to island Reil (from aphasia of transmissibilty).	No record.	.....	No record.	
39.	Kocher (*Brit. Med. Journal*, September, 1889, Correspondence from Berne).	.....	.....	....	Choked disk; amblyopia; headache; staggering.	....	Tumor of cerebellum.	Operation to relieve pressure; one opening posterior right side below tentorium, one anterior on left side; extreme tension dura; hernia cerebellum, removed with sharp spoon.	....	In four days congestion disks disappeared; no improvement of sight.	
40.	Keen (REFERENCE HANDBOOK MED. SCIENCES, Art. "Brain Surgery," 1889).	Boy, 4 years.	.. . .	....	Enlargement head; double optic neuritis; amblyopia.	None.	Tumor cerebellum pressing on straight sinus, causing internal hydrocephalus.	Tapping ventricles; trephined 1½ inch behind external auditory meatus (side not recorded), 1½ inch above Reid's base line; hollow needle and horsehair drain introduced; drainage fifty-two days; repeated probing brain; irrigation ventricles.	Tumor cerebellum, with density same as brain.	Diminution choked disks from day to day, but atrophy beginning.	Death fifty-two days after first operation.

41.	Keetley (*Lancet*, 1889, vol. ii., p. 593).	Child, 7 years.	Fall.	Fourteen days.	Giddiness; staggering; vomiting; knee-jerks exaggerated; attack of collapse, followed by subnormal temperature.	Slight internal strabismus left eye.	....	Exploratory operation through left squamous bone; nothing found.	Pons enlarged to three times natural size by infiltrating glioma; no inflammation or abscess; pons uniformly yellowish.	Insensibility; rigidity limbs, especially left arm; ptosis right upper eyelid; vomiting one-half pint black fluid; temperature 105.6° F.	Death in two days.
42.	Maudsley and Fitzgerald ("Trans. Intercol. Med. Congress, 1889").	Male, 28 years.	.....	.....	Headache; vomiting; vertigo, staggering; dim vision, blindness later; optic atrophy.	Awkwardness, left side; anosmia, left side; dilatation right pupil; slight paresis right facial; absence left knee-jerk; deafness left ear.	Tumor left lobe cerebellum compressing left facial and auditory nerves.	Trephined over left lobe cerebellum; solid nodule found, not removed; loss of much brain substance.	Solid nodule fixed to temporal bone.	Recovery, with persistent blindness and deafness.	
43.	Barton ("Ann. Surg.," St. Louis, 1889).	Woman, 30 years.	Syphilis; necrosis os frontis; abscess opened.	Symptoms brain pressure developed after operation on abscess.	Lethargy; confusion; anxiety.	Incomplete right hemiplegia; failure to find words for thoughts.	....	Trephined through necrosed bone; removed softening syphilitic gumma.	....	Immediate improvement in paralysis and speech.	Recurrence of drowsiness in three weeks; death in month, encephalitis.
44.	Lampiasi (*Wien. Med.*, May 19, 1889; from Knapp, loc. cit.).	Child, 2 years.	.....	.....	Convulsions; optic neuritis; exophthalmos.	....	.. ..	Trephining over cerebellum.	Tubercle size of egg in cerebellum.	Death in four days.	
45.	Horsley (*Brit. Med. Journal*, December 6, 1890). [Paper read at International Med. Congress, Berlin.] Ibid. (Three cases mentioned without details for record.)	No record.	None.	.....	Epileptic convulsions; attacks dyspnœa.	In fits, body rotated violently to left around central axis.	Tumor in middle lobe cerebellum.	Removed first one-half occipital bone; later, the other half.	.....	Abolition of dyspnœa, headache, and rotatory convulsion.	Life prolonged in comfort for two years.
46.	Knapp and Bradford (*Boston Med. and Surg. Journal*, April, 1890).	Male, 32 years.	....	.....	Vomiting three months in 1886; paresis both hands 1887, then convulsions; in 1888, headache; double optic neuritis.	Left hemiplegia and contraction left arm; exaggerated reflexes on left; operation advised, March, 1887; tactile left hemianæsthesia; loss muscular sense and paralysis left arm; paresis left leg; sensory aura in left wrist; clonic spasm left hand.	Tumor ascending frontal convolution below level first frontal sulcus, extending back and upward.	1889. Removed tumor; operation lasted fifty minutes.	Tubercle, 35¼ grms., middle right ascending frontal convolution.	Death from shock in three-quarters of an hour.	
47.	Springthorpe (*Austral. Med. Journal*, November 15, 1890).	Boy, 13 years.	Fall off five foot fence on right forehead.	Never well after fall; operation three years later	Severe headaches; gradual loss of sight; attacks vomiting; convulsions; vertigo; epistaxis; tottering gait; atrophy both optic disks; diminished knee-jerks.	Conjugate deviation head and eyes to right in fits; anæsthesia of formication in both hands; hearing right ear dull; falling toward right side and backward.	Cerebellar tumor.	Trephined over right lobe cerebellum: clear, serous fluid escaped; no tumor found.	At post-mortem, found glioma middle lobe cerebellum, with decomposing cavity in centre; numerous hemorrhages; all channels to lateral ventricles dilated; ventricles full of blood-stained fluid; cranial bones thinned; main pressure on right side.	Death.	
48.	Oppenheim (*Deutsch Med. Wochenschrift*, 1890).	Woman, 36 years.	.....	.....	Convulsions daily; headache; loss mental power; no choked disk; salivation; vomiting; six months pregnant.	Pain in right half of forehead; mouth drawn to right; paralysis left eyelid; total paralysis left arm; contracture; slight paresis left leg; sensibility blunted face and arm.	Cortical tumor lower part right ascending convolution.	Trephined; no pulsation; incised dura; anterior convolutions deep bluish red and swollen; opened into cyst; abundant serous fluid evacuated; no response to electricity over convolutions.	Glioma, with cystic degeneration.	Sensory and motor paralysis diminished next day.	Fairly complete recovery.

No. of case.	Operator, date, reference.	Sex and age.	Trauma or not	Time between trauma and first symptoms or duration.	General symptoms.	Localizing symptoms.	Diagnosis.	Operation.	Situation and nature of tumor.	First result.	Final result.
49.	Graham (*Austral. Medical Gazette*, June, 1890).	Boy, 15 years.	Fall over rock, ten feet.	Unconscious two days; first symptoms five years later.	Severe frontal headache; giddiness; nausea; attack vomiting, four days; blindness; post. neuritic atrophy; attacks drowsiness, etc.; coma begins just before operation.	Amaurosis left eye; leans to right side in walking; paresis right leg; protrusion eyes.	.....	Trephined over upper portion fissure Rolando. Entered cyst, evacuated, removed by traction.	Hydatid cyst; pia intact; motor area depressed; cyst had grown from arachnoid; capacity cyst, 19 oz.	Seventh day began to take interest; vicissitudes till fourteenth day; thence steady improvement.	Recovery, but with blindness.
50.	Church (*N. American Practitioner*, 1890, p. 433).	Man, 38 years.	.....	.....	Apoplectic seizure; afterward convulsions; constant frontal headache.	Fits begin with pain and spasm in right index finger, then other fingers, wrist, elbow, shoulder invaded by pain and clonic spasm; then loss consciousness and general convulsions; pain and contraction persist in right hand.	.....	Trephined over arm centre on left side. Area brain equal to silver dollar of central and frontal gyres decorticated to depth one-quarter inch.	Spider-shaped new growth, with long filaments on surface of convolution.	Next day aphasia, right motory and sensory hemiplegia: then twitchings in limbs preceded restoration functions; rise of temperature; a month later small abscess at wound.	Recovery, but convulsions recurred in two months.
51.	Sokes (*Brit. Med. Journal*, 1890).	Man, 42 years.	....	.....	Coma at time of operation; absence choked disk; fixed headache and vomiting.	Tonic spasms left side, beginning in leg, invading trunk, arm, face; then paralysis in same order.	Tumor at leg and arm centres.	Trephined over these centres; found nothing: operation relieved pressure.	Small spindle-celled sarcoma in parietal lobe, behind leg centre; same consistency as brain, remote from arm centre, yet arm engaged.	Recovery consciousness, and diminution paralysis.	Death in three weeks.
52.	Beach (*Boston Med. and Surg. Journal*, April, 1890).	Man, 51 years.	.....	.....	Severe frontal and occipital headache; mental dulness; double optic neuritis.	Short attacks of aphasia, without agraphia or loss of consciousness; tremor right hand; permanent hesitancy speech; twitching right hand and right eyelid; then paresis extensors right hand.	Tumor anterior lobe, pressing on lower part central convolutions.	Trephined; nothing found.	Tumor found on supposed level, but behind motor area: posterior edge limited by post. ascending branch of Sylvian fissure; anterior by small sulcus: motor and frontal convolutions healthy; optic tracts compressed.	... ...	Death second day.
53.	Wyman (*Med. News*, February 8, 1890).	Young man.	....	... ...	Frontal headache a year; fever several weeks' duration; diminished vision; double choked disk; vomiting; epileptic attacks; great muscular weakness.	Divergent squint after convulsion; slight movement retation; anosmia.	Tumor in region of sella turcica.	Trephined frontal bone above supra-orbital ridge on right side; probe passed along orbital plate; nothing found.	Tumor 2½ inches long, contained in a cavity in left hemisphere cerebellum; all ventricles distended with fluid.	Death.	
54.	Clarke (*Lancet*, March 1, 1890).	Man, 47 years.	Syphilis	Thirty years before symptoms.	Severe headache left side; several weeks; convulsions; unconscious three hours, then repeatedly; exaggeration reflexes both sides.	Initial paralysis, then paresis right leg; ataxia of torsion in right leg, then leg forcibly flexed; hemispasm; paresis right arm; recurrent twitchings and numbness right limbs; face drawn to right in fits; speech affected afterward, then slight motor aphasia	....	Trephined over upper part fissure Rolando, close to mesial line of skull; dura opaque, no pulsation; dense subdural growth, one-half inch thick; partial removal on account of proximity to sinus.	Very chronic syphilitic neoplasm growing from dura and falx cerebri.	Twitchings in foot for two days, did not spread; abscess formed in wound.	Death from septicæmia on nineteenth day.
55.	Walker (*Brit. Med. Journal*, Aug. 23, 1890).	Boy, 14 years.	Fall against tree in coasting.	Eighteen months before admission: first symptoms in three weeks after accident.	Dizziness, then paresis hands; staggering; mental power failed with speech; vomiting.	Hesitation in speech, then aphasia; hemorrhage right ear and mouth; offensive discharge right ear; series spasms left side; complete left hemiplegia (not left-handed); contracture: exaggeration left tendon reflex; hemianopsia not tested.	Tumor with descending sclerosis.	Exploratory operation over left ascending frontal; negative result.	Cystic mass at left of sella turcica springing from apex petrous bone.	Death in few hours.	

56.	Dumin (*Neurol. Centralblatt*, August 15, 1890; quoted by Knapp, loc. cit.).	No record.	.....	.....	.....	Hemiplegia; aphasia; Jacksonian epilepsy.	....	Trephined; removed tumor.	Tumor of anterior central convolution.	Recovery.	Sudden death four months after operation.
57.	Bremer and Carson (*Am. Jour. Med. Sciences*, September, 1890).	Male, 23 years.	.....	.....	Morning vomiting; peculiar gait; beginning choked disk; absence mental initiative.	Spasm left arm and neck; temporary aphasia; left hemiparesis with contraction in left foot; contractions platysma always begin spasm.	Cerebral tumor; slow growth in or beneath Rolandic region near centres for wrist and platysma.	Trephined over right fissure Rolando; tumor removed.	Cavernous angioma.	.....	Recovery.
58.	Kerr (*Occident. Med. Times*, 1890; from Knapp).	Male, 35 years.	Injury to head.	.....	... .	Right hemiparesis and spasm; scar over upper part fissure Rolando.	.....	Trephined over scar; nothing found.	Glioma left corpus striatum and optic thalamus.	.....	Death.
59.	Eskridge (from Knapp).	Female, 32 years.	.....	.....	Loss of strength, memory, mental power; headache.	Right hemiparesis, then hemiplegia.	....	Trephined, Feb. 25, 1890; tumor too large for removal.	Glioma, 3¾ x 4 in., in left frontal lobe, reaching beyond fissure Rolando.	.....	Death in eight days.
60.	Doyen (Congrès Français de Chirurgie, 1891).	Boy, 16 years.	.....	Symptoms seven years before operation.	Torpor of intelligence, gradually deepening to imbecility; vertigo, absences; epileptic attacks of increasing severity.	Left hemiparesis; diminution visual field on right side, then blindness and optic neuritis on this side; bulging right squamous bone.	Tumor of meninges or brain behind bulging bone compressing central convolutions.	Operation November 5, 1889, over bulging bone; very large cyst found; opened; drained.	Congenital serous cyst in locality diagnosed.	Drain withdrawn second day because causing bleeding; replaced sixth day, 360 c.c. albuminous liquid evacuated; then every three or four days till 50 c.c. left; permanent drain in six weeks; cure in two months.	Entire recovery; "marvellous expansion of intelligence;" disappearance of paralysis.
61.	Blocq and Reymer (Congrès Français de Chirurgie, 1891).	Boy, 10½ years.	.....	First symptoms five years before operation.	Crises, beginning at five years in prickling of facial mucous surfaces and increased secretion from conjunctiva, nose, and mouth; at eight years, falls: at nine, convulsive attacks, growing more intense; intelligence intact.	Attacks five to six times a day; mouth dragged to right, associated with prickling sensation at mouth and tongue: deviation tongue on right side, and bitten on right side; eyes fixed; head turned to right, then loss consciousness; right arm raised in flexion and adduction, then leg, then general convulsion after attack; right hemianæsthesia; temporary paralysis right arm.	Partial sensitivo-motrice epilepsy; neoplasm at inferior and middle third central convolutions.	Operation, August 19, 1890. Localization according to Poirier; cyst found extending toward frontal convolutions; wall excised; drainage. Second operation, removed cyst, volume of large walnut, December 13th.	.....	Attacks returned in sixteen days; after second operation patient well for six days, then attack followed by aphasia for two hours.	Recovery; no further attacks three and one-half months after operation.
62.	McCall Anderson (*Brit. Med. Journal*, 1891).	Boy, 16 years.	....	Four and one-half years before admission.	Sudden epileptic attack; second fit eighteen months ago, then others; at first arrested by bromides, then eighty-nine attacks in ten weeks; double optic neuritis; increased excretion earthy phosphates.	Exaggerated reflexes wrist and knee on left side; slight left facial paralysis; numbness and pain left thumb and index; acute pain above right ear, tenderness two inches behind; paresis left arm and leg.	Tumor at Horsley's thumb centre, junction middle lower third right parietal convolution.	Trephined just behind line for Rolandic fissure, three inches from upper extremity; at first found nothing; second trephine higher up; then brain substance bulged at first opening; tumor size of plum rolled out.	....	No epileptic attack for eight weeks; still some spastic contraction muscles fingers, wrist, elbow, but power to move arm.	Perfect recovery.
63.	Seguin (*Boston Med. and Surg. Journal*, February, 1891; from Knapp).	.....	.....	.....	No record.	....	Tumor under motor centre for left leg.	Trephined; nothing found.	Glioma, one-half inch in diameter, found at autopsy at point diagnosed in medullary substance below cortex; same consistency as brain.	....	Death.
64.	Bullard and Bradford (*Boston Med. and Surg. Journal*, April 30, 1891).	Female, 6½ years.	....	.....	Vomiting; vertigo; staggering; weakness all four limbs; incoördination; blindness; optic neuritis; headache.	.....	.....	Trephined over tornia; opening made into sinus.	Cheesy tubercle in cerebellum.	.....	Death from hemorrhage.

No. of case.	Operator, date, reference.	Sex and age.	Trauma or not.	Time between trauma and first symptoms or duration.	General symptoms.	Localizing symptoms.	Diagnosis.	Operation.	Situation and nature of tumor.	First result.	Final result.
65.	Knapp and Bradford (Case xxix. of "Essay," 1891).	Male, 28 years.	.....	.....	Headache; vomiting; optic neuritis; blindness; paræsthesia mouth and hands; deafness; anosmia.	Tenderness in right temporal region; absence left knee-jerk; slight paresis left hand.	....	Trephined over tender spot; nothing found; operation only to relieve intracranial pressure.	Tumor involving left lateral lobe of cerebellum.	Relief from headache; cerebral hernia; left hemiplegia and left anæsthesia.	Death from encephalitis about ten weeks later.
66.	Mills and Keen (*Amer. Journal Med. Sciences*, 1891).	Female, 27 years.	First symptoms ten years before admission.	.....	No optic neuritis; no general symptoms.	Left hemiparæsthesia for few moments; attacks at intervals weeks or months; in four years complicated by spasm left limbs, then passing to right; most marked in arm; prickling sensation left arm; cry; extension left arm, this leg; head twists to right.	.....	Trephined 1.75 inch to right of median line, in line of fissure Rolando; cranial index = 0.75; tumor removed.	Small growth, originating in pia, had bored through dura and formed nest in skull. one-sixteenth inch in front of trephine; Faradisation just behind fissure elevated shoulder; above opening Faradisation gave same, also flexion leg and thigh; growth looked like hypertrophied Pacchionian body, but proved sarcoma.	Movement left shoulder paralyzed; all paralysis disappeared on thirty-third day, though limbs weak.	Same attacks continued, but less severe.
67.	Koehler and Oppenheimer (*Berlin klin. Wochen.*, 1891).	Woman, 36 years.	Attack apoplexy one year before admission.	.....	Epileptic attacks; loss of memory; irritability; headache; vertigo; no optic neuritis.	Incomplete left paresis; then paralysis left arm; paresis left leg; knee-jerk exaggerated on left side; attack begins with drawing mouth to left; drawing in left arm, thumb, and index; then clonic convulsion arm; paralysis left half face.	Lesion right motor zone.	Operation while patient six months pregnant: trephined over lower part right parietal convolutions; dura did not pulsate; no reaction to electricity; swollen convolution over cyst; evacuated, anterior part removed.	Cyst size of hen's egg; cystic degenerated sarcoma.	Headache ceased; paralysis left facial; paresis left leg disappeared; arm recovered; normal delivery. At autopsy several months later softened tumor found size of apple in cortex and medullary substance of lower part central convolutions; interstitial encephalitis.	Typical epileptic attack four months after. Death.
68.	Keen (*Amer. Journal Medical Sciences*, Sept., 1891).	Man, 56 years.	Injury to head.	Eighteen years; first symptoms two years before admission.	Headache; nausea; vertigo; diminished vision; vomiting attacks; double optic neuritis.	Aphasia; right lateral hemianopsia; lesion left side brain; right hemiparesis; apraxia.	Tumor parieto-occipital lobe in angular gyrus, with pressure on left cuneus.	Trephined 1.3 ctm. behind parieto-occipital fissure, 3.2 ctm. to left of median line; dura bulged; no pulsation; no response to Faradic current; elastic hard body 6.3 ctm. below surface; some pieces removed.	Tumor size of filbert, 5 ctm. from end of occipital lobe, 2.5 ctm. from median line; angular gyrus removed at operation; infiltrating glioma.	.....	Death in fourteen hours.
69.	Castro ("Ann. Surgery," St. Louis, 1891).	Boy, 14 years.	Five months.	.....	Headache; vomiting.	Atrophy right leg and arm; reflexes exaggerated on left; pain on left side head.	.....	Trephined over fissure Rolando; removed tumor.	Blackish tumor size of walnut.	Bulging wound on seventh day; on twelfth day cicatrix opened; cyst, 7 ctm. ejected.	Death, from diphtheria of wound.
70.	Poirier (*Rev. de Chir.*, 1892).	Man, 32 years.	.....	Epileptic attacks twelve years, every fortnight.	....	Jacksonian epilepsy.	.....	Removal tumor through hole made by mallet and chisel.	Tumor; central gyri vascular.	.....	Recovery; freedom from attacks.
71.	Booth and Curtis (Neurological Society, New York, December 6, 1892).	....	.....	.....	General epileptic convulsions; marked psychic changes; choked disk, bilateral.	Anosmia on left side; bone eroded at angular process left frontal bone.	.....	Trephined over eroded bone; tumor removed.	Tumor, tuberculous.	.....	Recovery.

72.	Llobet (*Revue de Chirurgie*, December, 1892).	Boy, 13 years.	.....	Two yrs.; headache.	Headache violent: abolition intelligence and memory; crying and anger; exaggerated patellar reflexes; pulse slow; respiration slow and irregular.	Jacksonian epilepsy two months after headache; total hemiplegia right side; contracture in flexion forearm and fingers; right leg in flexion; foot in equinus varus; diminution vision right eye; mydriasis.	Tumor in psychomotor centre left hemisphere.	Resection temporal bone: flap 8x10 ctm.; no pulsation brain; fluctuation; evacuated 260 grms. fluid; extracted cyst.	Hydatid cyst.	Disappearance headache, epilepsy, hemiplegia, contracture, aphasia; reflexes became normal, also pulse and respiration.	Recovery, but memory not returned in three months.
73.	Nelson Dobson (*Lancet*, May 14, 1892).	Girl, 18 years.	.....	Ten weeks.	Cerebral vomiting; pain in forehead; blindness six weeks; intense double optic neuritis.	Twitching attacks in left arm, beginning in thumb and first finger; sensory aura in same parts.	.....	Trephined over Rolandio fissure; nothing found.	Multiple cerebral tubercles in right hemisphere; disseminated tuberculosis.	Hernia cerebri.	Death in a month.
74.	Hitzig (*Berlin. klin. Wochenschrift*, July 18, 1892).	Man, 29 years.	Blow on head.	.....	Headache; incipient dementia. choked disk; narrowed visual fields; paresis both legs; exaggerated both patella reflexes; mental symptoms preceded motor.	Paresis left hand in repeated attacks; diminished vision of right eye; paresis left facial; head inclined to left; paresis left arm; swelling soft tissues; over right temporal region of head, tenderness.	Tumor posterior part frontal lobe, adjacent to middle and lower part ascending frontal convolution on right side.	Trepanned at point indicated; high grade hyperostosis; skull one centimetre thick; tumor found; opening enlarged to 16 ctm. long and 9 ctm. broad; successful removal.	Tumor, 280 grms., equal to weight of half a hemisphere; sarcoma.	Facial paresis and deviation tongue persist; paralysis arm increased.	Recovery.
75.	Ibid.	Man, 46 years.	Blow on right side head.	Eighteen months before admission; first symptoms in ten days after blow.	Consciousness intact; no general symptoms; paresis both lower extremities; increase patellar reflexes.	Paresis index finger, then thumb and middle finger; later, convulsion left side, then paralysis hand, arm; paresis left facial, left vocal cord; tongue pushed to left; ankle-clonus left side.	.....	Trephining discovered cyst size of goose egg, proved to be an encapsulated cysto-sarcoma; removed in second operation.	.....	....	Recovery.
76.	Von Brammann (*Wien. Med. Wochens.*, 1892).	No record.	Fall on head.	Eighteen months previous to admission.	....	Paresis three fingers left hand, arm, and left half face; twitchings.	Tumor at fissure Rolando.	Trephined; bluish cystic tumor perceived through dura; 30 grms. clear serum withdrawn; drainage.	Round-celled sarcoma.	Recovery after first operation; recurrence in three weeks; second and third operation; at last tumor removed.	Recovery persists three months after operations.
77.	Ibid.	No record.	Blow on head in former years	.....	Persistent headache; diminished vision; diminished mental power.	Sudden weakness in left hand; gradual paralysis left arm and left face; neuritis left eye.	Tumor Rolandic area.	Trephined; tumor extirpated; temporary collapse.	Spindle-cell sarcoma; small cyst.	.....	Recovery.
78.	Nixon (*Med. Press and Circular*, 1892).	Man, 28 years.	History of syphilis.	....	Giddiness; vomiting; amnesia; defective vision; intense headache; double optic neuritis; dulness; paresis sphincters. (These symptoms all sudden.)	Left hemiplegia; suppurating sebaceous cyst; exposed bone over right parietal eminence.	.....	Operation over exposed bone; neoplasm incompletely removed.	Hard cartilaginous neoplasm adherent to superior longitudinal sinus.	Marked improvement; disappearance pain, paralysis, and sphincter paralysis.	Death fifth week, from secondary hemorrhage from wound.
79.	Clegg (*Liverpool Med. Chir. Journal*, 1892).	Man, 31 years.	... .	.....	Exophthalmos, double optic neuritis: severe amblyopia; convulsion after temporary aphasia.	Aphasia and right hemiplegia; temperature one degree higher on left side: eye suppurates; after first operation epileptic attacks, beginning in right side face, right arm; rarely right leg.	.....	Eyeball removed; inside, spindle-cell sarcoma surrounding optic nerve; second operation three months later; trephined over speech area; no tumor discovered; threatened collapse.	.....	Jacksonian epilepsy continued; temporary recovery after second operation.	Return of pain and attacks in four months.
80.	Twynam (*Australasian Medical Gazette*, May, 1892).	Man.	Fall on buttocks.	Six weeks.	Giddiness five minutes after fall; headache in six weeks.	Paresis left hand and leg; some loss sensation; pain in right temporo-frontal region.	....	Trephine over upper part right ascending parietal; no bulging, but after needle ʒij. straw-colored fluid; no tumor found.	Tumor occupying whole medullary centre right parietal lobe, 68 by 57 mm.; extends from Rolandic fissure to parieto-occipital, bulging into roof lateral ventricle.	Bronchitic râles; death on fourth day.	

Case No.	Operator, date, reference.	Sex and age.	Trauma or not.	Time between trauma and first symptoms or duration.	General symptoms.	Localizing symptoms.	Diagnosis.	Operation.	Situation and nature of trauma.	First result.	Final result.
81.	Starr and McBurney (New York Academy Medicine, January 5, 1893).	Man.	...	.....	Marked psychic symptoms; sluggish thought and speech; headache; double optic neuritis; no failure vision; motor symptoms developed later; exaggerated reflexes both sides.	Tenderness on percussion left side head; right side hemiparesis.	Tumor frontal lobe impinging on motor centres.	Trephined; removed very large glioma sarcoma. (Operation proposed eleven months before finally performed.)	.....	Shock; death in few hours.	
82.	Ibid.	Man.	...	.....	Optic neuritis; blindness; staggering; severe headache.	Exaggerated reflexes on right side; some right anæsthesia of face.	Tumor right lobe cerebellum.	Trephined with apex of flap on superior curved line; no tumor found.	Tumor in middle lobe cerebellum.	Relief from headache.	Death sudden in few days.
83.	Ibid.	Child, 12 years.	....	.....	Vomiting; headache; blindness; choked disk; staggering.	No local symptoms.	Tumor middle lobe cerebellum.	Trephined between curved lines; cystic tumor tapped; could not be removed.	Cysto-sarcoma middle lobe.	.....	Death in few days.
84.	Gray and Wyeth (*Brain*, 1892-93).	Man, 38 years.	.....	Symptoms one month before operation; hard growth in Scarpa's triangle.	Headache; insomnia; cremaster reflex sluggish on both sides; somnolence before operation.	Paralysis right leg; paresis right arm; *muscular sense greatly impaired*; other sensibility preserved; exaggeration right knee-jerks.	Tumor left centrum ovale (Subcortical, because no convulsion) beneath upper part ascending parietal convolution.	Operation November 14, 1890. Laid bare ascending frontal, ascending parietal convolution, one-half, bases 2d and 3d quarter of an inch beneath surface, at 1st and 2d parietal junction of upper and middle third; had been penetrated by exploring needle.	Round-celled sarcoma size of hickory nut in ascending parietal convolution, one-quarter of an inch beneath surface, at junction of upper and middle third; had been penetrated by exploring needle.	.....	Death third day after; temperature, 108° F. for an hour.
85.	Stieglitz & Garster (Neurolog. Soc., Jan., 1893).	.....	.....	.....	.....	Twitching, then paresis right arm; loss of muscular sense; alexia.	Tumor arm centre.	Opening over left Rolandic area; cyst evacuated.	.....	Recovery, but slight symptoms recurrence six months later.	

Out of the 300 cases of tumor in children, 96 were situated in the cerebellum. This single fact suffices to establish a relatively unfavorable prognosis for brain tumors in childhood.

In this same list were found 56 cases of tumor of the cortex and centrum ovale, localities favorable for operation; 16 of these, however, were not correctly diagnosed, therefore could not have been operated, even if the operation had been suggested.

Out of the 40 which remain, localizing diagnosis would have been impossible in 21, though the autopsy showed that in some of them an operation would have been possible. In 19 cases the tumors were in the central convolutions, or subjacent centrum ovale, and in 13 of these local spasm followed by paresis made the precise diagnosis sufficiently clear. In the remaining 6 the locality was established by the symptom hemianopsia. The author estimates, however, that in only 16 of these cases could an operation have been undertaken with much hope of success, and as 10 of these were tubercular, the number of cases where even this new and heroic remedy offered hope of complete recovery was reduced to 6 out of a total of 300.

The statistics for adults, as regards localization, differ somewhat from the above. A table of 649 cases, compiled from the cases of Ladame and Bernhardt, has already been given in the article on "Brain Tumor" in the main body of this HANDBOOK. It may be worth while to reproduce this table. The tumor was situated in the:

		Per cent.
Centrum ovale in	192 cases	= 29
Cerebellum in	162 "	= 27
Cortex in	74 "	= 11
Pons in	56 "	= 8
Basal ganglia in	26 "	= 5
Medulla in	30 "	= 4
Corpora quadrigemina in	13 "	= 2
Cerebral peduncle in	10 "	= 1
Extra cerebral in	71 "	= 11

This table can be compared with Starr's as follows:

Tumors situated in	Children.	All cases.
Cerebellum	96 cases = 32%	162 cases = 27%
Cortex and centrum ovale	56 " = 18%	266 " = 41%

Thus consideration of the prevailing situation of brain tumors alone, would seem to justify Bergmann's dictum,[1] that the field for successful operation is very narrow, the reverse of what can be now affirmed of trephining for brain abscess. On the other hand, examination of the 85 cases in which operations have been performed gives a more favorable view. At this date (January, 1893) there is a record of 39 successful operations against 46 unsuccessful cases, and one trephining to relieve intracranial pressure.[2] These have been performed in all parts of the world, even British Guiana having contributed a successful case in 1888 (Rannie, *British Medical Journal*, 1888). The following table summarizes these results. "Successful" implies that the tumor was found and removed, that the serious symptoms subsided and the patient lived more than two months, or even recovered completely. "Unsuccessful" refers, not only to the death of the patient from the immediate consequences of the operation, but also to the impossibility of completing this, either because the tumor was not found at the locality supposed, or proved too large or too deeply seated to be completely removed; finally to the speedy recurrence of the tumor so as to cause the death of the patient in a short time, notwithstanding the immediate success of the operation.

Successful		39
Unsuccessful:		
Tumor not found	20	
Tumor not removed	10	
Death from operation or speedy recurrence of neoplasm	16	46
		85

In 1888 Dr. Keen wrote (REFERENCE HANDBOOK, "Brain Surgery") that the percentage of mortality was thirty-five per cent. This calculation was based upon the 17 operations which had then been performed, with six recoveries, and included among them one case (Heath, *Lancet*, 1888, Case 27 of table), which we have placed among the unsuccessful cases, because, although the patient survived the operation and was relieved, the tumor was too large for removal. The percentage of successes (11 cases out of 17) was nearly sixty-five. To-day, the larger number of cases yields as successful about forty-six per cent., as failures, nearly fifty-four per cent. The less favorable result is not surprising, for the operation has been attempted under a much greater variety of circumstances, so that a greater number of unfavorable conditions have been encountered. For this reason the estimate of the operation has varied in the same way as did that for tracheotomy. This operation on its first suggestion excited unbounded enthusiasm, until experience showed how numerous conditions of failure were inherent in the disease for which the operation was performed, and which could not be overcome by any degree of perfection in its surgical technique.

The precision is surprising with which small tumors have sometimes been localized for removal. In Seguin and Weir's case (No. 24) the neoplasm was only the size of an almond, and lay an inch below the surface. In another case, however, reported by Seguin, a glioma one-half inch in diameter escaped detection. It was found at the autopsy at the locality diagnosed, under the motor centre for the left leg, but its consistency so resembled that of the brain tissue that it could not be differentiated (Case 63). The writer remarks that an operation may be undertaken too early on the brain—*i.e.*, before the tumor has grown sufficiently large to be appreciable, even although it may have occasioned pathognomonic symptoms.

In 19 other cases where the tumor was not found, the reason for the failure was quite different. In Keetley's case (41) the pons was found enlarged to three times its natural size by an infiltrating glioma. The only localizing symptom presented had been a slight internal strabismus of the left eye (paresis abducens). This fact should have suggested a pontine, and consequently inoperable tumor, as also the fact that the knee-jerks were exaggerated, while absence of paralysis, and existence of vomiting, giddiness, and staggering pointed to a tumor of the cerebellum.* With the latter, however, the knee-jerks are habitually diminished, and this special combination of negative and positive signs should suggest a lesion of the pons, in spite of the absence of many of its characteristic paralyses. The patient, a child of seven, who had had a fall fourteen days before the onset of the symptoms, had an attack of collapse followed by a subnormal temperature just before the operation, another circumstance pointing to the pons. An exploratory operation was made through the left squamous bone, but nothing found, and the child died two days later.

In Pilcher's case (31) there was a scar after an injury situated over the left angular gyrus, and the skull was trephined at this point. The patient had marked mental impairment, epileptic attacks, beginning in a conjugate deviation of head and eyes to the left, and tonic hemispasm on the right side. Shafer (*Brain*, April, 1888) claims that excitation of the brain near the angular gyrus produces conjugate deviations of the eyes to the opposite side. The centre for such deviation is placed by Horsley at the posterior extremity of the middle frontal gyrus; and the autopsy in this case would seem to confirm that localization. A glioma was found on the left side, in the occipital lobe, but extending forward as far as the frontal lobe. The island of Reil was softened. The mental impairment, taken together with the conjugate deviation of the eyes, pointed to the frontal lobes, where also the headache was situated. Nothing indicated the occipital lobe, and at the angular gyrus nothing was found. In Sciammana's case (3) also the patient was trephined, unsuccessfully, at the seat of an injury to the head in the right parietal region. The tumor was a glioma, lying in the right centrum ovale and extending from the right inferior cornu to the corpora quadrigemina. Crossed paralysis had existed, left hemiplegia, followed by right oculo-motor and facial paralysis. This is not explained by the autopsy.

Kerr's operation (58) is the third on the list misled by a scar. The indication was the more plausible because the scar was situated over the upper part of the left fissure of Rolando, in a patient suffering with hemispasm and hemiparesis. A glioma was found in the left corpus striatum and optic thalamus. This is the only case on the list where a tumor in this situation had simulated a cortical tumor.

In Knapp's second case (65), the trephine was applied over a tender spot in the right temporal region, although there were well-marked symptoms of a cerebellar tumor. After death, ten weeks after the operation, the tumor was found in the left lateral lobe of the cerebellum. In this case the left knee-jerk was absent, and there was slight paresis of the left hand, symptoms which, together with the characteristic symptoms of tumor, might have sufficed to indicate the cerebellum.

In seven other cases an erroneous diagnosis was made of tumor of the cortical motor centres (Fraser, Hammond, Amidon, Stokes, Walker, Dobson, Twynam), and in one (Beach) of tumor of the frontal lobe pressing on the central convolutions (Cases 5, 7, 8, 51, 55, 73, 80).

In Fraser's case (5) the localizing symptoms were right hemiplegia and contracture, indistinct speech, amnesic aphasia, agraphia. The error depended on the duplicity of the lesion. There was a tumor in the middle of the right ascending parietal convolution, and another in the left temporal lobe involving the ascending convolutions. The amnesic character of the aphasia really pointed to the left temporal lobe rather than to the neighborhood of Broca's convolution. It is difficult to understand the failure in Hammond's case (7), as the autopsy revealed three cysts in a line in the anterior central convolution precisely where the lesion had been diagnosed. In Amidon and Weir's case (8) the tumor was found in the cerebellum at the autopsy, although the patient had had left hemispasm and paralysis of the left arm. Two circumstances, however, pointed to the cerebellum—with the left-sided paralysis co-existed a paresis of the right arm, thus a bilateral motor defect, and there was also optic neuritis on the left side. Stokes's case (51) shows, as the author remarks, that the motor centre for the leg extends farther back than is usually assumed, or else that transmitted pressure from a distance may cause the same symptoms as a lesion at the centre. A spindle-celled sarcoma was found in the parietal lobe, just behind the leg centre, and being of the same consistency as the brain, could not be distinguished.

In Walker's case (55) the symptoms were very confusing. Staggering seemed to indicate a cerebellar tumor, as also the vertigo and vomiting. But a marked mental defect pointed to the frontal lobes, and motor aphasia to a lesion on the left side. On the other hand, left hemispasm and hemiplegia were to be referred to the right side of the brain, and hemorrhage and an offensive discharge from the right ear seemed to localize the disease more precisely near the petrous bone. Paresis of both hands pointed to the cerebellum; exaggeration of the left tendon reflex, on the contrary, confirmed the indications offered by the left hemiplegia. An exploratory operation was performed over the left ascending frontal with negative result. At the autopsy a cystic mass was found at the left of the sella turcica, springing from the apex of the petrous bone. The record leaves unexplained why this should have been associated with discharge from the right ear.

Dobson's case (73) exhibited an apparently exquisitely precise symptom, namely, twitching attacks in left arm, beginning in thumb and first finger, with sensory aura in

* The knee-jerks are usually diminished in tumors of the cerebellum, whereas they are exaggerated in tumors of the pons. This may be a useful detail in distinguishing between these two lesions, whose symptoms often resemble each other.

same parts. Horsley has located the thumb centre just behind the middle of the ascending parietal convolution, and a signal symptom in Jacksoniam epilepsy, initiated at this point, has several times guided to an exact diagnosis. But in this case the centre was evidently irritated by pressure from a distance. There were multiple cerebral tubercles in the right hemisphere. This is the second case of multiple tumor on the list.

In Twynam's case (80) the tumor seems to have escaped detection, partly because it lay too far below the surface in the medullary substance, partly because, as in Stokes's case, the tumor, though pressing on the central convolutions, lay behind them, in the parietal lobe. Besides the hemiparesis there was some loss of sensation, and this symptom, as well as the loss of muscular sense, seems to point to the parietal lobe rather than the central convolutions. Another fact in the same sense was the incomplete nature of the paralysis. The tumor found on autopsy was very large, 68 by 57 millimetres, extending from the Rolandic fissure to the parieto-occipital, and bulged into the roof of the lateral ventricle.

In Beach's case (52), finally, a tumor was diagnosed in the left frontal lobe, pressing on the lower part of the central convolutions. The first local symptom had been a motor aphasia, followed by tremor, then twitching of right hand and eyelid, then paresis of right hand. The tumor was found at the supposed level, but, as in Cases 51 and 80 (Stokes and Twynam), it lay in the parietal lobe behind the motor convolutions and between the posterior ascending branch of the Sylvian fissure and a small sulcus anteriorly which separated it from the ascending parietal convolution. There were no sensory symptoms to aid the diagnosis.

In Wille's case (25) a tumor of the left parietal lobe was diagnosed, but the diagnosis was guided by the existence of a swelling over the left parietal bone. Only after this had been incised did right hemiparesis appear, including the facial nerve. In a second operation subdural pus was evacuated but no tumor was found. At the autopsy was discovered a tumor the size of a pigeon's egg in the posterior part of the left paracentral lobule, extending into the upper part of the ascending parietal convolution. Also, and this makes the third case of multiplicity, a second tumor was found in the middle of the ascending parietal convolution. In two other cases on this list the tumor lay in the cerebellum. In Wyman's case (53) it had been diagnosed in the sella turcica, because, in addition to the general symptoms, the patient had a divergent squint (paralysis motor oculi), anosmia, and slight movement of rotation at the beginning of the convulsive attacks. There was great muscular weakness, but neither hemiplegia nor staggering. A tumor three-quarters of an inch long was found in a cavity hollowed out in the left hemisphere of the cerebellum. All the ventricles were distended with fluid. The great frequency of cerebellar tumors might, it would seem, have decided the surgeon to operate, if at all, in their locality. But instead of this he trephined the frontal bone above the supra-orbital ridge and passed a probe over the orbital plate to the sella turcica with necessarily negative result.

In Springthorpe's case (47) a cerebellar tumor was correctly diagnosed, and several symptoms pointed to pressure on the right lobe of the cerebellum. In the fits there was conjugate deviation of the head and eyes to the right side; the right ear was moderately deaf, and the patient fell backward and to the right side. An opening was made over the right lobe of the cerebellum, clear serous fluid escaped, but no tumor was found. At the

TABLE II.—*Twenty Cases of Operation where Tumor was not Found.*

No.	Name.	Diagnosis.	Real locality.	Result.	Remarks.
68	Seguin.	Tumor under motor centre for left leg.	Locality diagnosed.	Death.	Tumor very small, half inch in diameter, and of same consistency as brain.
41	Keetley.	No record.	Infiltrating glioma of pons.	Death in two days.	Symptoms pointed to cerebellar tumor, but exaggerated knee-jerks, attack of collapse, and subnormal temperature.
3	Sciammana.	Trephined over a scar or tender point.	Right centrum ovale.	Death in two days.	Symptoms not explained by autopsy.
31	Pilcher.	Trephined over a scar or tender point.	Occipital lobe.	Death.	Conjugate deviation eyes, pointed either to angular gyrus or upper part frontal lobe; latter affected by pressure.
58	Kerr.	Trephined over a scar or tender point.	Basal ganglia.	Death.	Hemispasm and hemiparesis fully simulated a cortical tumor.
65	Knapp and Bradford.	Trephined over a scar or tender point.	Cerebellum.	Death.	Symptoms indicated a cerebellar tumor, because general symptoms marked, left knee-jerk absent, and paresis left hand.
84	Gray and Wyeth.	Tumor in Rolandic convolutions.	Tumor of centrum ovale one-fourth inch below surface of ascending parietal convolution.	Death in three days; much exploration of brain by needles.	Failure due to identical consistency of neoplasm and brain-tissue.
5	Fraser.	Tumor in Rolandic convolutions.	Double lesion: first, ascending parietal: second, temporal lobe.	Death.	Amnesic aphasia really indicated temporal lobe or island of Reil.
7	Hammond.	Tumor in Rolandic convolutions.	Triple lesion, but all in motor convolution.	Death in twenty-one hours.	Failure to find three cysts is not explained.
8	Amidon and Weir.	Tumor in Rolandic convolutions.	Cerebellum.	Death in ten weeks.	There was bilateral motor defect and left optic neuritis, which might have suggested cerebellar lesion.
51	Stokes.	Tumor in Rolandic convolutions.	Parietal lobe, just behind leg centre.	Death in three weeks.	Symptoms very confusing, but included discharge from ear.
55	Walker.	Tumor in Rolandic convolutions.	Apex petrous bone.	Death in few hours.	
73	Dobson.	Tumor in Rolandic convolutions.	Multiple tubercles in hemisphere.	Death in one month.	Apparently characteristic cortical epilepsy.
80	Twynam.	Frontal lobe, pressing on motor convolutions.	Parietal lobe.	Death fourth day.	Some loss of sensation might have suggested superior parietal lobule.
52	Beach.	Frontal lobe, pressing on motor convolutions.	Parietal lobe.	Death second day.	In this case no sensory symptoms, and motor aphasia had preceded hemispasm.
25	Wille.	Parietal lobe (scalp swelling here).	First, in paracentral lobule; second, in ascending parietal.	Death.	
53	Wyman.	Sella turcica.	Left hemisphere of cerebellum.	Death.	Many cerebellar symptoms, but also paralysis abducens and anosmia.
47	Springthorpe.	Cerebellum, right hemisphere.	Middle lobe cerebellum.	Death.	Pressure on right side localized the symptoms.
82	Starr and McBurney.	Right lobe cerebellum.	Middle lobe cerebellum.	Sudden death in few days.	
40	Keen (REFERENCE HANDBOOK MEDICAL SCIENCES, 1889).	Tumor cerebellum.	Cerebellum.	Death in fifty-two days.	Tumor diagnosed but not sought; ventricles tapped for internal hydrocephalus.

autopsy a glioma with a central cavity was found to occupy the middle lobe of the cerebellum. All the ventricles were full of blood-stained fluid. The main pressure was upon the right side.

The last case has just been reported by Gray and operated by Wyeth (84). The exact locality of the tumor was correctly diagnosed, but it lay one-quarter inch below the surface (as had been expected from the absence of convulsions), and the consistency so closely resembled that of the medullary brain-tissue in which it was embedded that an exploring needle passed through it without detecting its presence, and it was discovered at the autopsy with difficulty, and by careful slicing of the brain.

Nearly all the cases where the tumor was not found at the site of operation proved fatal, the operation seeming to accelerate the natural march of the disease. One case, however (Amidon and Weir), survived ten weeks, another (Dobson) a month. Four cases illustrate the now accepted rule, that a scar, and still less a tender point on percussion, must not be selected as a site of operation, unless focal symptoms point to the same locality.

In the five cases of cerebellar tumor a retrospect of the symptoms, after the autopsy, makes them seem more significant than they had appeared before the operation. Cases 47 and 53, as do many other cases which have not been operated, show the impossibility of distinguishing with certainty whether a tumor of the cerebellum be situated in its lateral or its middle lobe. Nothnagel's law of the frequent latency of tumors of the lateral lobes should always incline the diagnosis in favor of a central lesion, unless lateral symptoms are very well marked. The danger of hemorrhage, however, from trephining over the centre of the cerebellum, *i.e.*, of the sinus, is very great, and, on the other hand, a tumor of the middle lobe is sometimes accessible from the side.

TABLE III.—*Tumor not Removed, Temporary Recovery.*

45	Horsley.	Tumor middle lobe cerebellum; removal occipital bone in two operations.	Life prolonged in comfort for two years.
27	Heath.	Large adherent growth over ascending frontal convolution.	Relief and prolonged recovery.
35	Limont and Page.	.....	Temporary recovery; recurrence of growth.
39	Kocher.	Tumor cerebellum diagnosed.	Double trephining relieved intracranial pressure, arrested optic neuritis.
49	Maudsley and Fitzgerald.	Tumor a solid nodule fixed to temporal bone.	Recovery with persistent blindness and deafness.

TABLE IV.—*Tumor not Removed, Fatal Cases.*

15	Birdsall and Weir.	Sarcoma at tip of occipital lobe; softened contents removed.	Death from hemorrhage in a few hours.
54	Clarke.	Subdural growth over upper end fissure Rolando adherent to longitudinal sinus; partial removal.	Death from septicæmia on nineteenth day.
59	Eskridge.	Glioma left frontal lobe reaching beyond fissure Rolando; too large for removal.	Death in eight days.
78	Nixon.	Bone necrosed over tumor; operation at this point; neoplasm is completely removed; cartilaginous, adherent to longitudinal sinus.	Death fifth week from secondary hemorrhage from wound.
83	Starr and McBurney.	Cysto-sarcoma middle lobe cerebellum; tapped but could not be removed.	Death in a few days.

Operation on tumors too large for removal, when the cranial opening was really made over the seat of the lesion, have not always proved so dangerous as in the class of cases just described. Thus, Horsley (Case 45) removed first one half of the occipital bone, then the other, where an inoperable tumor of the middle lobe of the cerebellum existed. The patient had suffered for a long time from epileptiform fits, with violent rotary movements, from severe headache and distressing attacks of dyspnœa. All these symptoms disappeared after the operation, and the patient's life was prolonged in comfort for two years.

In Heath's case (27), also, a large adherent growth was found over the right ascending frontal convolution, which could not be removed. Localized tenderness had existed over the site of the tumor. The patient was relieved of his headache by the operation, and, at the time of reporting, had made a good recovery. In Case 35 (Limont and Page) a portion of a large glioma was removed, with temporary recovery, but the growth recurred.

In Case 39 (Kocher) tumor of the cerebellum was diagnosed from the four classical general symptoms, in the absence of focal symptoms. A double trephine opening was made to relieve intracranial pressure, one posteriorly on the right side below the tentorium, one anteriorly on the left side. In four days congestion of the optic disks had disappeared, but there was no improvement of vision.

In Maudsley's case (42) a tumor had been diagnosed in the left lobe of the cerebellum, the trephine was applied at this locality and a tumor found, but it was a solid nodule, irremovably attached to the temporal bone. The patient recovered from the operation. Five other cases proved rapidly fatal. The entire list of ten cases is summarized in Tables III. and IV.

Death occurred after removal of the tumor in sixteen other cases. The causes may be thus tabulated:

TABLE V.—*Tumor Removed with Fatal Result.*

1	Bennett and Godlee.	Glioma upper third Rolandic fissure.	Hernia cerebri; septic meningitis; death in thirty days.
4	Hirschfelder and Morse.	Infiltrating glioma post central gyrus.	Death eighteenth day; septic encephalitis.
12	Horsley.	Tubercle right lobe cerebellum, seven drachms.	Death in nineteen hours from shock; general tuberculosis.
13	Bennett May.	Tubercle size of pigeon's egg in cerebellum.	Death from shock.
14	Suckling.	Tumor left and middle lobes cerebellum.	Death from shock in forty-eight hours.
22	Von Bergmann.	Cyst in Rolandic region communicating with lateral ventricle.	Death in four weeks from meningitis.
32	Wood and Agnew.	Right temporo-sphenoidal lobe.	Death from hemorrhage.
34	Thomas.	Tumor, three ounces, middle central convolutions.	Death in three days.
37	Verco.	Hydatid cyst adherent to temporo sphenoidal lobe.	Death from meningitis with temperature 104° F.
43	Barton.	Rolandic gyri syphilitic gumma with necrosed bone.	Death in a month from encephalitis.
44	Lampiasi.	Tubercle size of egg in cerebellum.	Death in four days.
46	Knapp and Bradford.	Tubercle, 35¾ grms., middle ascending frontal convolution.	Death from shock in three-quarters hour.
64	Bullard and Bradford.	Cheesy tubercle in cerebellum.	Sinus opened; death from hemorrhage.
68	Keen.	Tumor size of filbert five centimetres from end of occipital lobe.	Death in fourteen hours.
69	Castro.	Tumor size of walnut over Rolandic fissure.	Death from epidemic diphtheria affecting wound.
81	McBurney and Starr.	Very large glio-sarcoma from frontal lobe.	Death from shock in few hours.

Five out of these 16 cases are tumors of the cerebellum. Five cases on Table II., one on Table III., and one on Table V., were also cerebellar; thus 12 out of the total number of 46 unsuccessful cases, or twenty-six per cent.

The death from diphtheria (Castro) and that due to accidental opening of the cerebellar sinus (Bullard and Bradford) are theoretically avoidable. The case of glio-sarcoma removed by McBurney had been correctly diagnosed eleven months before, and the operation then advised. At that time it might have been successful, so that in this case the fatal issue may fairly have been attributed to the delay. It may perhaps be assumed that

the five deaths caused by septic meningo-encephalitis could have been avoided by more perfect antiseptic precautions.

The fatal issue is not clearly explained in the cases reported by Gray, Thomas, and Keen. The last case is particularly interesting, because the tumor had been correctly localized in the cuneus on account of the symptom of hemianopsia. It is the only case in the entire collection where this symptom was thus rendered available.

In 39 cases the operation was successful. The situation of the tumor in these cases is shown in the next table.

TABLE VI.—*Successful Cases.*

Number.	Name.	Diagnosis and Operation.	Locality.	Result.
2	Macewen.	Tubercular membranous mass removed from right ascending frontal gyrus.	Rolandic region.	Recovery complete.
10	Horsley.	Upper part middle third Rolandic region.	Ibid.	Recurrence tumor in three months; death in six months.
9	Ibid.	Tumor thumb centre in ascending parietal gyrus.	Ibid.	Complete recovery; disappearance of epilepsy and paralysis.
11	Ibid.	Tumor hand centre pressing on Broca's convolution.	Ibid.	Recovery; persistence, but arrest of hemiplegia.
17	Macewen.	Tubercle size of hazel-nut top of ascending parietal.	Ibid.	Recovery.
18	Ibid.	Cyst size of filbert base of left ascending frontal gyrus.	Ibid.	Recovery.
19	Ibid.	Yellow mass over upper part right ascending convolutions.	Ibid.	Recovery.
20	Lucas Championnière.	Large hyperostosis over left ascending frontal convolution.	Ibid.	Recovery, with persistent hemiplegia.
21	Rannie.	Degenerating gumma from right ascending frontal. Piece of dura and brain removed.	Ibid.	Recovery, with cessation symptoms.
23	Seguin and Weir.	Sarcoma size of almond one inch below posterior edge second frontal and anterior edge precentral gyrus.	Ibid.	Perfect health six months after operation; signs of recurrence later.
29	Pean.	Growth from dura over left ascending convolution; fibro-lipoma.	Ibid.	No more epileptic attacks two months after operation.
30	Fisher.	Sarcoma pressing on left central convolution.	Ibid.	Recurrence of tumor two months after operation and death.
38	Mercanton. and Combe.	Tumor middle left ascending frontal reaching to island of Reil.	Ibid.	No record, but presumed recovery.
48	Oppenheim.	Glioma in cystic degeneration lower part ascending convolution.	Ibid.	Complete recovery.
49	Graham.	Hydatid cyst upper portion fissure Rolando.	Ibid.	Recovery, with blindness.
50	Church.	Spider-shaped sarcoma over left arm centre; decortication one-quarter inch.	Ibid.	Recovery; recurrence epilepsy in two months.
56	Dumin.	Anterior convolutions.	Ibid.	Recovery; sudden death in four months after operation.
57	Bremer and Carson.	Cavernous angioma at fissure Rolando.	Ibid.	Recovery.
62	McCall Anderson.	Tumor at thumb centre right parietal convolution.	Ibid.	Perfect recovery; no attack for eight weeks.
66	Milla and Keen.	Small sarcoma from pia pressing upon central convolutions.	Ibid.	Recovery; diminished severity attacks.
72	Llobet.	Motor convolutions. Resected temporal bone.	Ibid.	Recovery, only memory not returned in three months.
61	Reynier and Blocq.	Cyst over central convolutions extending to frontal gyri.	Ibid.	Cyst drained in first, removed in second operation; no attacks during three and one-half months.
60	Doyen.	Very large cyst behind bulging bone.	Ibid.	Cyst drained for six weeks, 360 c.c. fluid at one time.
70	Poirier.	Vascular tumor central gyri.	Ibid.	Recovery; freedom from epilepsy.
29	Pean.	Right leg centre.	Ibid.	Recovery; cessation epilepsy at two months.
75	Hitzig.	Cyst size of goose-egg.	Ibid.	Recovery.
76	Von Brammann.	Cystic tumor at fissure Rolando. Drained twice; removed at third operation.	Ibid.	Recovery.
77	Ibid.	Spindle-celled cysto-sarcoma in Rolandic area.	Ibid.	Recovery.
85	Stieglitz and Gerster.	Tumor arm centre.	Ibid.	Recovery, but symptoms recurrence six months later.
16	Markoe.	Hemorrhage cyst over parietal lobe; depression skull.	Parietal lobe.	Recovery.
33	Parker.	Gummous tumor size of walnut under right parietal eminence.	Ibid.	Recovery on eightieth day.
24	Keen.	Fibroma base third frontal convolution, reaching to fissure Rolando.	Frontal lobe.	Recovery eighty-fourth day; epileptic attack five weeks later.
6	Durante.	Fibro-sarcoma, 70 grammes, in anterior fossa.	Ibid.	Prompt recovery, persisting four years after operation.
74	Hitzig.	Tumor, 280 grammes, posterior part frontal lobe.	Ibid.	Recovery.
79	Clegg.	Exophthalmos; removal sarcoma with eyeball.	Ibid.	Return of pain and attacks in four months.
26	Fitzgerald.	Echinococcus behind left temple.	Ibid.	Recovery.
28	Macewen.	Nodule on skull between ascending convolution and frontal lobe.	Tumor of dura at frontal lobe.	Recovery for eight years.
71	Booth and Curtis.	Erosion of bone at angular process frontal.	Tubercle frontal lobe.	Recovery.
36	Maunsell.	Cyst four inches long, three inches broad.	Cerebellum.	Recovery; blindness persists.

These cases of recovery include one, and only one, case of tumor of the cerebellum, and that was a cyst. This is to be reckoned against 12 fatal cases of cerebellum tumor, already noted. As might be expected, in the immense majority of successful cases the tumor is situated in the motor convolutions (29 out of 39 cases). This region unites all the conditions of success, facility of diagnosis, facility of operation, relative freedom from danger of shock. Among the unsuccessful cases the tumor was situated in the central convolutions only 7 times, and in one of these the death was purely accidental, due to an epidemic diphtheria. In all the others death was due to septic meningitis, in one case, also syphilitic. In one a communication existed between the tumor and the ventricle; in another, there was an adhesion to the longitudinal sinus.

The symptoms of lesion of the central convolutions are so well marked that when the tumor exists in this locality it cannot easily be overlooked. It sometimes happens, however, that tumors in other localities simulate the symptoms proper to disease in the cortical motor centres. Thus: 1. The tumor may be situated in the subcortical region of the centrum ovale, as in Gray's case (84). The diagnosis in this case, notwithstanding the monoplegia, was correctly made as subcortical, on account of the absence of spasm or convulsion. 2. The

tumor may lie in the frontal, parietal, or temporal lobes, and by transmitted pressure excite the symptoms proper to the motor area. The diagnosis, when possible, is made out by observing that lesions of intelligence, or speech, or sensibility, or vision, especially hemianopsia, have preceded motor symptoms, and that the latter remain incomplete—paresis, not paralysis. 3. Tumor of the basal ganglia may simulate cortical tumor. This occurred in Case 58 (Kerr). It is rather surprising that the mistake has not been made more frequently. That it has not, is due to the enormously valuable studies in "Jacksonian epilepsy," that may be ranked as the second link in the chain of investigation which, beginning with the researches of Hitzig and Ferrier on brain localization, have so rapidly led to brain surgery. Only one tumor of the occipital lobe has been operated at its site, the diagnosis having been guided by the remarkable symptom hemianopsia (Birdsall and Weir, 15).

In Pilcher and Dana's case (31) the tumor occupied the left occipital lobe, but the operation was made at the site of a scar corresponding to the angular gyrus. The tumor, therefore, was not found. It is not stated whether the patient was examined for hemianopsia.

It is claimed, especially by Starr, that an onset of symptoms with psychical changes is very characteristic of tumors of the frontal lobe. Such mental depression, however, is apt to occur with intracranial tumors in any locality, and cannot be considered a distinct indication of frontal lobe localization until, by extension backward, motor symptoms began to complicate the mental; or until conjugate deviation of head and eyes has become a signal symptom in convulsive attacks; or until anosmia be discovered. In several of the frontal lobe tumors here recorded an external lesion coexisted and guided the operator to the exact locality.

It seems to have become accepted that a fairly large opening through the skull is preferable to the small trephine openings originally chosen. With such large flaps much greater facility is offered for detecting a tumor, whose remote pressure symptoms had confused the preoperative diagnosis (see Gray's case).

From the foregoing record of cases we may deduce several propositions, which, collectively, contain the sum of new knowledge acquired in the treatment of brain tumors during the past decade.

In the first place, it has been demonstrated that it is practicable to open the cavity of the cranium, to penetrate the dura mater, to lay bare the brain, and even to excise portions of its tissue. The successful removal of brain tumors has restored to favor as a legitimate surgical procedure the old operation of trephining, which had fallen into desuetude.* So far this surgical restoration has proved more useful in other cases of brain disease than in that which is the subject of this chapter (see chapter on "Brain Surgery"). But the fact will always remain interesting, that it was the greater exploit of excising a cerebral neoplasm, which has, in entirely modern times, encouraged surgeons to the lesser effort of trephining for cerebral abscess and traumatic hemorrhage; and revived the old rules of unhesitating trephining in traumatic cases with depressed fracture.

Again, when Hughlings-Jackson first began to study the precise order of development of the sensori-motor phenomena in the class of convulsive attacks which now bears his name, their habitual dependence upon organic brain lesion had not yet been established. This has now been shown, and the cases of brain tumor attended by attacks of Jacksonian epilepsy have assumed the most favorable prognosis, because the fact of the attacks usually indicates that the tumor is situated in the cortex of the central convolutions, and from the details of the attack the exact motor centre may be inferred. Pursuing still further the line of thought, neurological surgeons have argued that if a tumor in the motor area determines a definite series of explosive symptoms—sensori-motor irritation, followed by sensori-motor paralysis—the occurrence of such symptoms, apart from indications of intracranial tumor, implies that the same motor region is irritated, though in some other way than by a neoplasm. Many cases of epilepsy, hitherto considered a functional disease,* have therefore been trephined, and in many of these, organic lesions, as cicatrices, have been removed from the surface of the brain or meninges, with the result of allaying or arresting the convulsive attacks. Finally, even in the absence of all visible lesion, portions of cortical tissue have been excised containing the centres of motor representation corresponding to the limb segments whose spasm initiates the attack.

It is not within the province of this article to discuss this latest and most interesting development of surgical method, which began with removing the tangible organic causes of epilepsy. We may observe, however, that the signal symptom of the attack (the felicitous expression is Seguin's), which is held to localize the lesion, because indicating the point of earliest and most intense irritation, does not necessarily show that the irritation originates at this point. It is quite as possible that the nerve-tissue has received an irritation propagated from some distant region, but not manifest until it has spent itself upon a motor centre and thence determined a nervous discharge. Excision of the motor centre, therefore, would not remove a cause of the spasm, but only the first effect, of some possibly inaccessible cause.

From the frequent failure of the operation as a cure for epilepsy one may suspect that some such condition of things often exists. The difficulty in these non-organic cases is paralleled in cases of tumor, where, though the convulsions are immediately initiated by irritation of the cortical motor area, the causal lesion is situated in some other part of the brain and cannot be found.

Another parallel has a more hopeful aspect. It has been sometimes found in cases of inoperable tumor that the symptoms due to pressure—vomiting, headache, and convulsions—could all be relieved when the pressure was lessened by trephining or removal of large pieces of cranial bones.† It seems therefore possible that in cases of epilepsy without gross or focal lesion, and before irremediable degeneration had set in, similarly afforded relief of intracranial pressure might arrest the disease.

Traumatism, even when not more severe than that of a fall on the head, has always been recognized as an important factor in the etiology of brain tumors. Out of the 85 cases of operation on record, there is a history of a fall or a blow in 20.‡ Morbid symptoms rarely develop very soon after the accident: months, sometimes years, intervene. In the light of the experience now accumulated, it is indicated to operate very early after the appearance of symptoms indicative of intracranial neoplasm; and the indication is especially formal if there is a history of previous traumatism. It is possible, as Seguin's case shows, to operate so early that the tumor has not yet grown large enough to be found at the operation. This is, however, the only case on the list where the operation failed from this cause; only when the tumor is situated entirely on the surface of the cortex is it liable to excite convulsive twitchings while yet very small; but in such a situation the tumor should be easily found.§ The danger of delay in operating is well shown in the first case of Starr and McBurney (Case 81). Eleven months intervened between the establishment of the diagnosis (when the operation was first proposed) and the time when the patient's consent to the operation was secured. In that time the tumor grew to such a size that its removal was followed by death from shock in a few hours.

* Horsley, in a learned lecture, claims to have found evidence of operative trephining on the skulls of prehistoric men.

* According to the present view, non-localizable, *i.e.*, generalized epilepsy depends upon a diffused microscopic sclerosis (Feré, Les Epilepsies) or a degeneration and vacuolation of ganglion cells (Dana, Treatise on Nervous Diseases).

† Horsley (see Case 45) removed first one half, then the other half of the occipital bone, "and the patient lived in comfort two years."

‡ Cases 1, 3, 5, 16, 18, 24, 31, 37, 38, 41, 49, 55, 58, 68, 74, 75, 76, 80, 82. Case 38 is particularly interesting. It is that of a little girl in a Swiss school who was struck on the head with a ruler by her teacher.

§ In Case 50 (Church) the tumor was a spider-like, filiform growth, extended on the surface of the central and frontal gyri.

The development of optic neuritis is not always proportioned to the size of the tumor, but much more to its situation. Hence, as has long been known, optic neuritis appears early and advances rapidly with tumors of the cerebellum, where the intracranial pressure is at its maximum. An early operation is often indicated to relieve this pressure before the optic nerves should have atrophied, in which case the patient would remain blind, even though he survived the operation and were relieved of other urgent symptoms.*

An important decision formulated by Horsley is that syphilitic tumors should be operated on, and not left to the uncertain influence of internal treatment. Bergmann, on the other hand, maintains the sufficiency of this treatment, and the superfluous risk of the operation.

If it be assumed that all tumors of the cortex and centrum ovale are conceivably operable, the proportion of operations to cases would be forty-one per cent., since 266 out of 649 cases of tumor are situated in these two localities. If to these be added 162 cases of the cerebellum the proportion would rise to sixty-five per cent. (table quoted on p. 132).

The special difficulties surrounding tumor of the cerebellum have already been emphasized. The general diagnosis is relatively easy, that is, it is usually easy to diagnose a tumor of the posterior cranial fossa and subtentorial. It is often difficult to distinguish between the middle lobe of the cerebellum and a lateral lobe; and usually impossible to distinguish between tumor of the bone compressing the cerebellum and tumor of the organ itself. A precious aid in diagnosticating tumors of the occipital lobe from those of the cerebellum is the existence of hemianopsia in the former, as against optic neuritis in the latter. Case 41 (Keetley) shows how a tumor of the pons may be mistaken for a cerebellar tumor, when by exception the paralyses of cranial nerves, so characteristic of pontine tumors, are lacking. The prognosis in cerebellar tumors, however, is rendered bad, far less by the difficulties of diagnosis, than by the special dangers of the operation which have already been mentioned. In the centrum ovale and cortex, on the contrary, the dangers of the operation are at the minimum, provided the tumor can be found. The difficulty of finding it depends upon: 1st, whether it lie in a latent zone or in one whose symptomatology has been determined; 2d, upon its proximity to the surface; 3d, upon the differentiation of its consistency with that of the brain.

The accessible regions of the cerebrum whose lesions have so far been connected with sufficiently definite differential symptoms, are as follows:

Frontal lobes: †	Marked and primary impairment of intelligence.
Posterior and second frontal convolution.	Spasmodic conjugate deviation head and eyes to side opposite lesion at beginning of epileptic attack; agraphia (?).
Left third frontal convolution.	Motor aphasia; anosmia on side of lesion (sometimes); secondary incomplete irritative or paralytic motor symptoms as tumor extends backward; exophthalmos, unilateral (sometimes).
Central convolutions.	Spasm, followed by paresis or paralysis, both permanent or intermittent, and occurring in attacks of Jacksonian epilepsy or as signal symptoms in general convulsion, in one or more segments of face or limbs innervated from the known motor-centres.
Parietal lobe:	
Anterior convolutions or superior parietal lobule.	Incomplete symptoms of irritation or paresis of motor symptoms, usually developed after general symptoms of brain tumor; diminished sensibility; loss of muscular sense.
Posterior convolutions:	
Angular gyrus.	Apraxia (?).
Occipital lobe:	
Cuneus.	Homonymous hemianopsia. Staggering, ataxia, from pressure on cerebellum (sometimes).
Temporal lobe:	
First convolution.	Sensory aphasia; motor spasm and paresis as tumor grows upward.
Tip of lobe.	Combination of motor aphasia from pressure on Broca's convolution, with sensory aphasia.
Island of Reil.	Aphasia of transmissibility.

Tumors of the centrum ovale are always latent, unless they become very large, or are near enough to the surface to affect the cortex. By lesion of the motor tracts they cause paralysis unpreceded by spasm. Two cases are recorded (cases of Sciammana and Gray) where tumors of the centrum ovale escaped detection at operation.

In Sciammana's case (3) the locality was not diagnosed, and the trephine applied over a misleading scar. In Gray's case (86) the position was made out with great precision, but the failure was due to the third operative difficulty which has been mentioned, namely, the soft consistency of the tumor.

This difficulty can never be foreseen in advance, and seems to be as great with large as with small tumors. Possibly some future therapeutic resource will enable the surgeon to prepare his patient for operation by the ingestion of some food or drug which should change the consistency of the tumor.

For details of cranio-topography, operative procedure, and technique, and the special dangers incident to the operation for brain tumor, the reader is referred to the article on "Brain Surgery," by Dr. Keen, in Vol. VIII. of the REFERENCE HANDBOOK.

Mary Putnam-Jacobi.

[1] Surgical Treatment Diseases of Brain, translation from Berlin edition, in Wood's Medical and Surgical Monographs, 1890, New York.
[2] Horsley, British Medical Journal, 1890, reports without detail several such cases of similar trephining.

BRAIN, VESSELS OF THE. ARTERIES, *Medidural.*—The furrows of the medidural artery on the entocranial wall deepen with years, and in old age the artery sinks quite into them. It has two primary branches, a larger cephalic and a caudal, the former again soon (at the sphenoidal angle of the parietal bone) separating into two secondary rami. The anterior ramus runs up behind the coronal suture, though a little more obliquely, being, according to Marchant, pretty constantly from 0. to 13 mm. (averaging 5 to 6 mm.) away at the foot of the suture, about 1 ctm. at its middle, and 15 mm. at its dorsal part. The second ramus starts on the entotemporal surface 4 ctm. behind the pterion, on an average. At its middle, on the entoparietal surface, it averages 54 mm. behind the coronal suture. Farther dorsad, the distance is very variable, 30 mm., more or less.

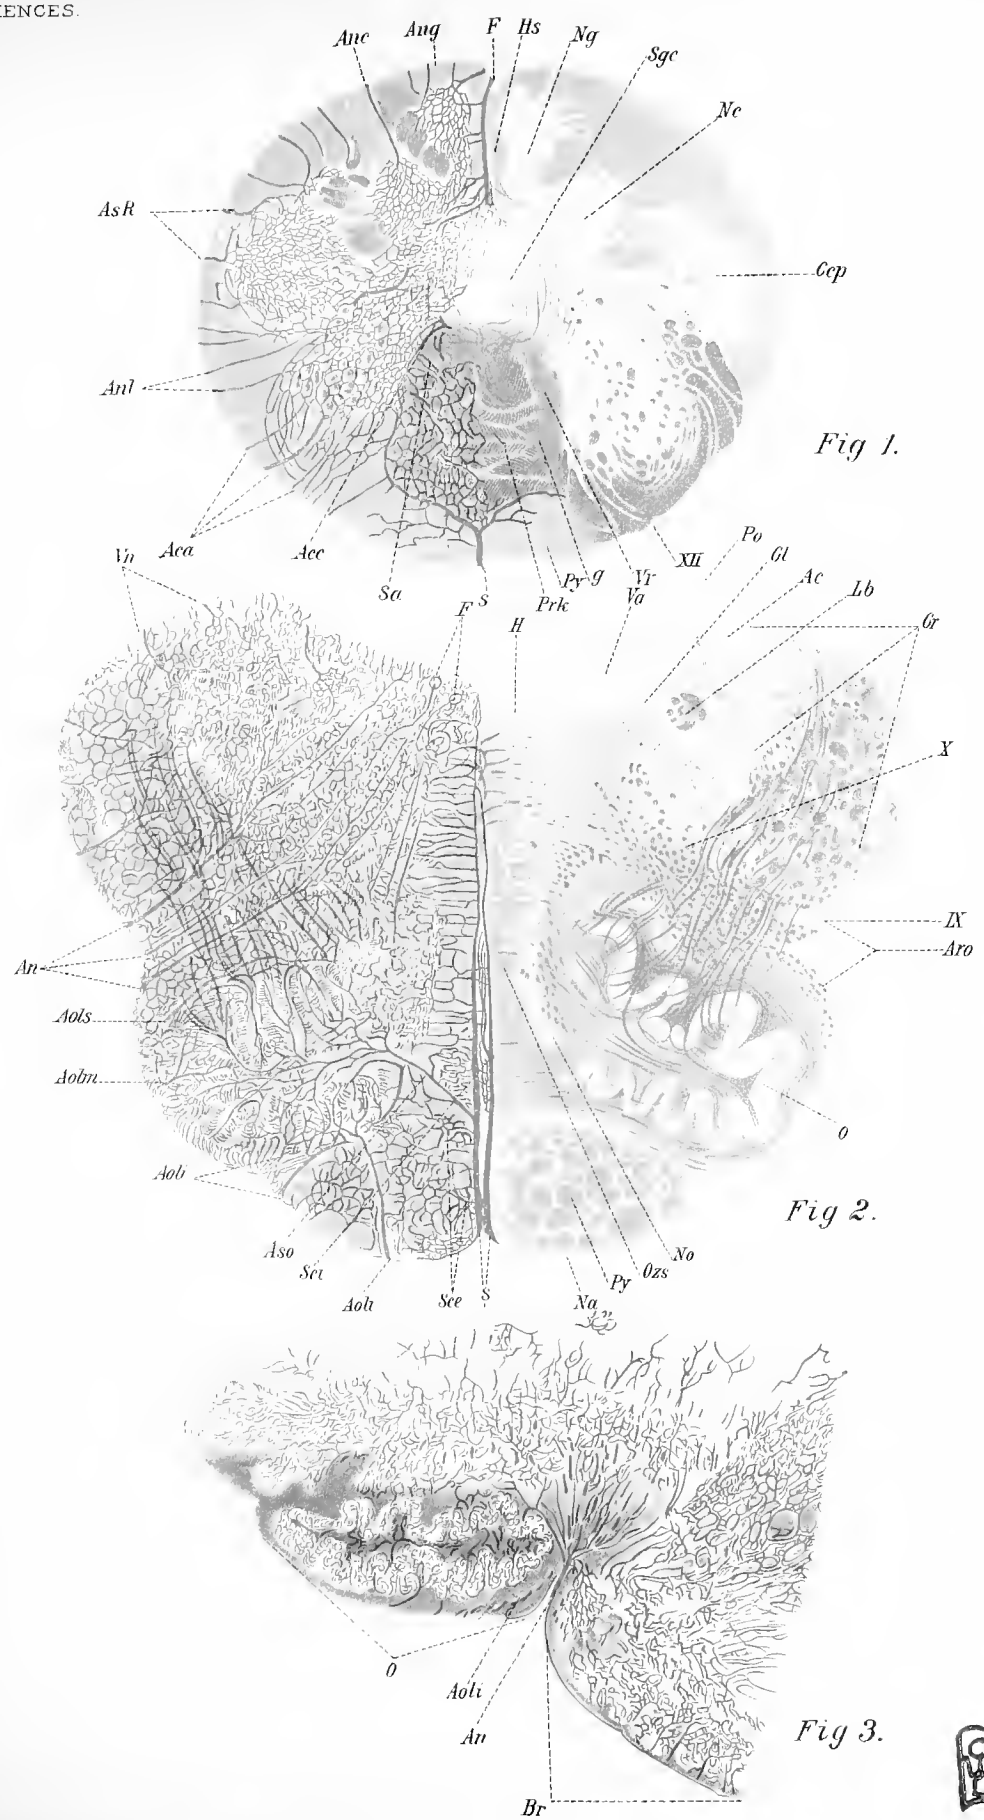
The primitive caudal branch leaves the temporal squama 58 mm. behind the pterion, then goes toward, and becomes parallel with, the lambdoidal suture.

The relations of these vessels to the subjacent cortex, important clinically, Duchaine sums up thus: 1. The cephalic branch runs up opposite the frontal lobe some ctm. before the central fissure, rather nearer the coronal suture. 2. The mid-ramus starts almost opposite the fissure, then runs up some ctm. behind it. 3. The caudal branch is always a ctm. or more distant from the fissure, and is still further separated above.

Variations in the Basal Arteries.—Dercum offers "A Collection of Anomalies of the Circle of Willis" (*Jour. of Nerv. and M. Dis.*, 1889, Jan.), and J. H. Lloyd (*Ibid.*, 1890, p. 225) gives such a case of a type described by Duret (right vertebral absent, both precerebrals from left carotid, etc.). St. John Bullen (*Jour. Mnt. Sci.*, 1890, Jan., p.

* See Case 49 (Graham). In the article on Brain Tumor in the REFERENCE HANDBOOK it has been noted that choked disk is sometimes due to neuritis from diffused cerebritis, sometimes also to direct pressure on the optic tract.

† The following case illustrates the possible latency of a tumor of the frontal lobe: Boy, aged eight. Extensive joint disease right elbow and left tarsus. Thirty hours before death convulsion for the first time. Began on left side, with spasmodic closure eyelid, twitching in face, neck, arm, leg. Wave of convulsion then passed rapidly to right limbs. Examination, then made for first time, discovered double optic neuritis and anosmia. Death. Tumor, 3½ inches long, 2½ inches thick, at base of right frontal lobe, extended from one-half inch of tip of frontal lobe to point corresponding to section through bases of first and second frontal convolutions, one inch anterior to fissure of Rolando. Came to surface at junction of third frontal with orbital gyrus. The tumor lay immediately behind and external to the root of the olfactory nerve.



Arterial Supply of Oblongata (from Adamkiewicz.)

33) bases the following statements on the examination of 1,565 brains (from the insane), but holds statistics too uncertain. Arterial variations occur much oftener in general paralytics than in those dying of other forms—this applying equally to all segments of the circle of Willis. However, such anomalies are more common in the postcommunicants than in all the others. Of these vessels: 1, Either may be absent; 2, may be replaced by a branch from the subcerebellar, internal carotid, postcerebral, or two small nutrient branches respectively from the last two vessels; 3, may supply unusual regions; or, 4, may be unconnected with the carotid system.

The precommunicant may be absent, or merely rudimentary, or double. Either of the postcerebrals may, 1, be absent; 2, be a branch of the carotid system; 3, be replaced by a large postcommunicant; or 4, by two thread-like vessels from the basilar.

Either precerebral may, 1, be replaced by two small trunks; or 2, be absent, its region being supplied by branches of the opposite artery. Only occasional variations are attributed to the vertebrals: 1, absence of one, the existing vessel being joined by a branch from the opposite carotid; 2, both may join the basilar on the same side; 3, or one may be represented by two or three branches before entering the formation of the basilar trunk.

Prechoroid Artery.—In general Kolisko's work corroborates that of Heubner. In a large number of examinations this vessel was never absent. It has a pretty constant diameter of ½ mm. In the fœtus it is relatively very large. In animals (dogs, cats, rabbits) it was regularly present, but arose from the Sylvian. The branch to the uncus was always present, but has free anastomoses in the pia. The branches in plexus and tela also anastomose freely with others near; but those to the brain-substance are terminal.

The prechoroid supplies the following parts: The posterior arm of the internal capsule, with the lamina medullaris externa of the thalamus to the level of the upper angle of the mid-lenticular segment—usually only the posterior two-thirds; the white substance back of the internal capsule as far as the roof of the medicornu; the inner lenticular segment; the uncus; the optic tract (in its posterior half); the lateral choroid plexus; the endyma of the posterior and lower parts of the paracœle; the greater part of the tail of the caudatum; exceptionally the external parts of the upper half of the thalamus.

But the posterior arm of the internal capsule is also in part supplied by the medicerebral and postcommunicant (the anterior third of this part by the latter vessel), the deeper parts by the prechoroid and postcommunicant, and the upper parts (above apex of mid-lenticular segment) by the Sylvian (lenticulo-optic ramus of Duret).

Circulatory disturbances in the supply-territory of the prechoroid cause opposite hemiplegia by softening in the posterior segment of the internal capsule, involving the pyramidal and cranial-motor tracts.

Hemianæsthesia, hemianopsia, and hemianosmia may likewise follow closure of the prechoroid, but are usually headed off by collateral supply.

Where the postcommunicant is large, its blocking may cause opposite facial and hypoglossal paralysis, since these tracts traverse the front part of the posterior arm of the capsule.

Arteries of Oblongata.—The recurrent spinals from the vertebrals are given as follows by Kadyi. Immediately after the vertebrals traverse the dura there arises from each a 1 mm. thick branch (dorso-myelic), which, after giving up twigs to the restiform body, descends along the dorsal border of the lateral columns of the cord. This is homologous with other branches entering by the dorsal nerve-roots. Sometimes this arises from the vertebral in common with the postcerebellar.

Near the union of the vertebral to the basilar there arises—usually one on each side, though unequal—the myelic branch for the ventro-myel. These two, however, either soon or oftener after entering the spinal canal, combine to form the azygoid ventri-myelic artery. They are thus continuous and homologous with the other myelic arterioles coming in along the ventral nerve-roots.

A full consideration of the minute details of the arterial distribution in the oblongata is given by Adamkiewicz. These vessels come wholly from the upper (intra-cranial) part of the vertebrals as they cross the ventral surface of the oblongata.

The main facts regarding the three classes of secondary or nutrient arterioles (external or surface vessels) he accepts from Duret: 1. The radicals, direct from the vertebrals, supply the outgoing nerve-roots (facial, acoustic, glosso-pharyngeal, vagus, accessorius, and hypoglossus). 2. The nuclears, at right angles from the one or two dorso-myelics in an extent of 3 to 4 ctm. These penetrate the median fissure, at the bottom of which they form a kind of sagittal leader, and end beneath the floor of the metepicœle (fourth ventricle). 3. Arteries for the other portions of the oblongata (olivary bodies, pyramids, corpora restiformia), in part at least from the myelics.

Moreover, on the oblongatal surface is a rich net-work of vessels. The ventro-myelics opposite the oblongata give off a multitude of twigs that take a very sinuous course and soon settle into the furrows. For the dorsal surface of the oblongata there is no external supply until below the calamus—upper end of myel. Its source is the dorso-myelics. These latter, at the first cervical roots, turn caudad between the accessory nerve-roots (nearer the dorsal), and when at the level of the fourth or fifth cervical roots, they end by also anastomosing with vessels of lower origin.

From the middle portion of the vertebrals, between the ventro- and dorso-myelics, arise the largest branches (subcerebellars), but these dodge the oblongata and are wholly for the cerebellum.

Topographically, he distinguishes three sets of finer or nutrient arterioles (internal or substantial vessels) after the manner of the myelic supply. 1'. Ventro-fissurals, relatively large, dividing in the ventral commissure into two branches, one to each side for the corresponding ventro-mesal cinerea. In the oblongata these supply principally the pyramidal tracts and decussation, lemniscus, interolivary tract, raphé, and the following nuclei—gray dorsal columna, n. pyramidalis, n. arciformis, oliva, and hypoglossus.

2'. Dorso-fissurals, of course only caudad of the calamus. These divide at the dorsal commissure into two border vessels, and are for the substance of the dorsal columns, nucleus gracilis, accessorius centre, and casually the hypoglossus.

3'. Coronal, radial, or lateral system. These are very numerous, penetrate the alba from all sides (excepting of course the metepicœle), and in part reach the subjacent cinerea to then help form its mass of capillaries. A subclass here—nuclear arteries—consists of 6 to 8 relatively large twigs entering the angulus restiformia olivaris and running parallel toward the middle of the floor of the metepicœle, to supply principally the centres for glosso-pharyngeus, vagus, hypoglossus, and acusticus. The following parts receive these radial or lateral affluents—the ventral columns, lateral nuclei, lateral cornu, caput of substantia gelatinosa, nuclei cuneati gracilis, arciformis et pyramidalis, and the oliva itself.

Width of Brain-arteries.—To make a relative estimate of the capacity of the arteries at the base, Bevan Lewis ("Examination of Brain," 1882, pp. 20–22) determined their average diameters in 45 cases (insane). That of the vertebral was, r. 3.147 mm., l. 3.42; of basilar, 3.82; of postcerebral, r. 2.658, l. 2.56; of carotid, r. 3.951, l. 4.02; of medicerebral, r. 3.133, l. 3.55; and of precerebral, r. 2.73, l. 2.66. The sectional areas are of course proportional to the squares of these diameters. As a rule, the united areas of branches equal very nearly the area of the parent trunk—excepting the preponderance of the vertebrals over the basilar (22.4 to 14.8).

Lowenfeld has found that the relation of the artery-width to the brain-weight is, even normally, somewhat variable, and that often, though not by any means in all cases, the width of the brain-vessels rises and falls with the width of the aorta; moreover, that not rarely abnormally small brain-arteries occur in otherwise well-developed arterial systems. He also made out a difference

in the two sides, the left carotid being usually wider than the right.

Pressure in the Brain-arteries.—A further matter, noted by St. John Bullen (*l. c.*) may partially indicate the relative pressures in the main brain-arteries. He remarked atheroma of the basal vessels in 410 of 1,565 autopsies, or 26 per cent. of the total. It was present to a considerable extent, either generally dispersed, or in special trunks only, in 175 cases, and to a less extent in 235. The relative frequency by location was: medicerebral, 38 per cent.; basilar, 30 per cent.; postcerebral, 21 per cent.; carotid, 10 per cent.

Mendel (1891) has found experimentally that the pressure in the cortical arteries is materially less than that in the carotids, while that in the striatal arteries is not materially less. This he attributes to the fact that the latter are terminal vessels, though it is doubtless quite as much due to their less circuitous supply. He further thus explains the frequency of hemorrhage in the striatal region.

Tedeschi's conclusions regarding the brain-arteries refer in part to moot points, but really contain nothing new and are deceptive in statement.

Veins. — The careful work of Hédon traverses this field along approved lines, and represents largely a verification of the work of others.

Oblongata Region. — The ventro-mesal chain of myelic veins is continued cephalad on the ventral surface of the oblongata to the furrow between this and the pons, there connecting with a fine venous network over the surface of the latter (Kadyi). This plexus in turn also connects with the veins of the cerebellum and of the base forward.

Besides irregular smaller ones, there are in particular two constant and considerable veins passing from this plexus, one on either side along the trigeminal nerve to the sinus petrosus (or cavernosus).

From the above-mentioned chain on the ventral surface of the oblongata, between the pyramids, there frequently arises a little trunk (up to ½ mm. or more thick) that joins one of the hypoglossal root-bundles and passes out with it through the precondyloid foramen—doubtless a part of Luschka's plexus venosus hypoglossi.

The dorso-myelic chain of veins is continued cephalad over the oblongata. From a constant mesal vein here a small veinule traverses the arachnoid, covering the cisterna magna. Sometimes this adjoins the accessory nerve, and Kadyi thinks it probably empties into the sinus plexus about the foramen magnum.

Among the cerebellar veins Hédon, referring to Merkel, mentions one that "comes from the flocculus and empties into the superpetrosal sinus. An important branch of this vein rises from the interior of the cerebellum in the region of the dentatum, receives also veins from the cerebellar medi-peduncle, and emerges with the peduncle under the flocculus. The main trunk can acquire a very considerable size when it receives a branch of the basilar vein" (Precerebellar vein, Fig. 67).

Other Veins.—A point once described by the writer has recently (1889) been more carefully gone over by Mittenzweig. In 200 cases he found 59 in which the pre-supracerebrals (to only 9 in which the post-supracerebrals) jumped over from the piarachnoid to the dura at 3 to 4 ctm. from the long sinus—thus favoring their rupture, as he thinks.

The post-perforating veins come, according to Hédon, from the cinerea of the walls of the diacœle, and even from the mesal surface of the thalamus. He also claims that in the striate nuclei the perforating veins anastomose with those going toward the cavities and Galen's system. He further recognizes the communications in the medicornu between the choroidal and the infra-cornual veins.

Developmental.—From various peculiarities in the vascular supply of the human brain, more especially the caudad displacement peripherally of the post-supracere-

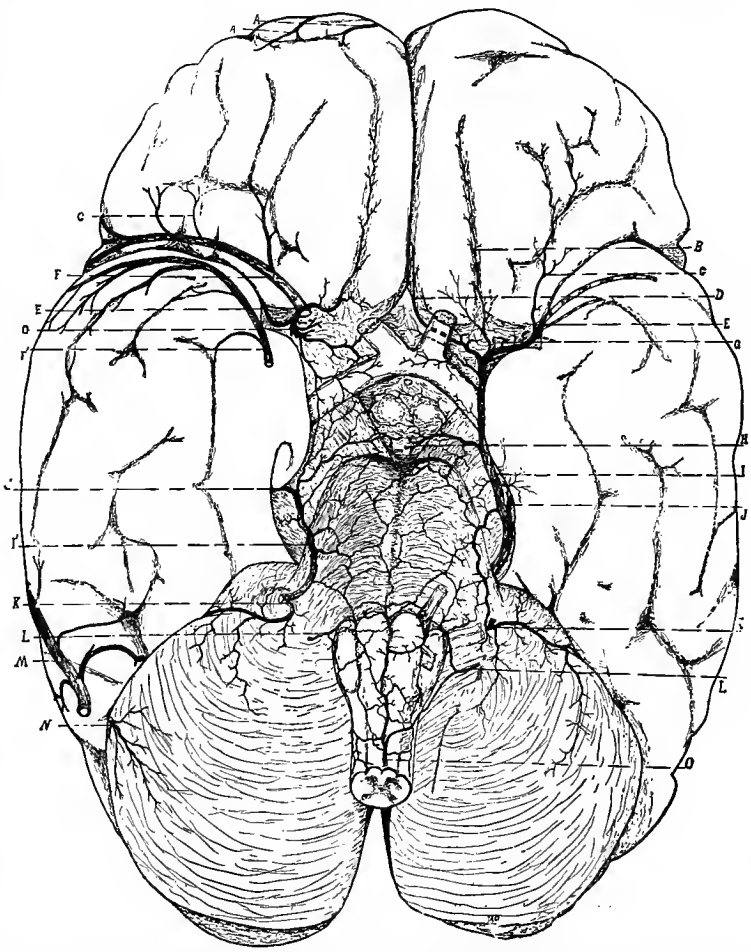


Fig. 67.—Veins of the Base (¾ nat. size). The two sides represent respectively the more common arrangements of these veins. Those of the myel and oblongata are largely after Kadyi. AA, supraccrebrals; B, ramus to olfactory bulb; CC, subfrontals; D, precerebral; EE, Sylvian or insular; F, medicerebral (to cavernous sinus); F′, post-medicerebral (per temporal sinus to superpetrosal); GG, preperforantes; H, postperforantes: I, subcerebral (to Galen's vein); I′, subcerebral (when emptying at base); JJ, subcornuals; KK, precerebellars; LL, hypoglossals (to precondyloid emissary); M, postcerebral (to lateral sinus); N, paracerebellar (to lateral sinus); O, ventrimyelic (anterior spinal).

bral veins, the writer has adduced evidence favorable in a general way to Hill's theory, and showing further that in any such rotation the brain and pia have glided caudad upon the dura and brain-case.

Here may be added a casual observation of a persistent fœtal form, made at the autopsy of a child of 22 months, dead of tubercular meningitis. The large left medicerebral vein took the temporal course in a deep groove (per temporal sinus, intradural), and passed out at the foramen jugulare spurium instead of passing to the supra-petrosal sinus, first, however, connecting with a much

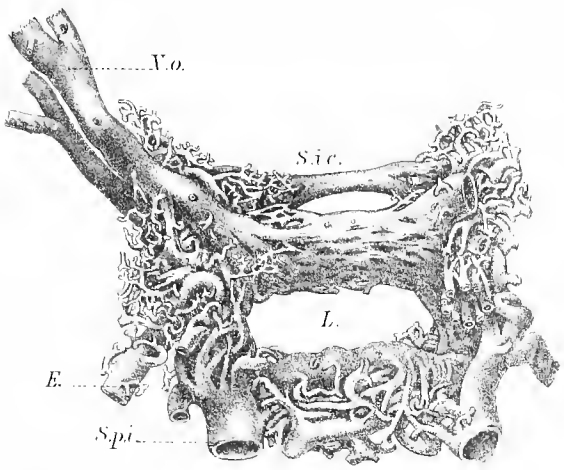

Fig 1.

smaller prepetrosal sinus. No such appearance on the right.

SINUSES. *Occlusion.*—By experimental blocking of the dural sinuses in the dog, Ferrari (1888) has shown that a large part of the whole sinus system, *e.g.*, all the sinuses of the calvarium may be rendered impermeable without injury to the functions of the brain. However, occlusion of the collective blood-efferents from the skull is of course quickly fatal, being usually preceded by an epileptic attack. But all this and more had been already determined by clinical experience in man.

Lateral Sinus.—Körner (1889) has shown that intracranial disease from caries of the petrous is more frequent on the right, and from a study of 449 skulls he attributes this to the fact that the lateral sinus at its sigmoid flexure enters deeper into the mastoid and the petrous pyramid on the right than on the left, and thus on the right approaches nearer the primary focus of disease. In 22 cases on the right and 8 on the left, there were gaps in the bony partition. He also holds that in the brachycephali the sigmoid excavation goes lower and deeper than in the dolichocephali, and that hence in the former such encranial sequelæ follow more readily; but this has been disputed by Schülzke.

Birmingham, of Dublin (*Brit. Med. Journ.*, 1890, ii., 683) from an examination of 100 recent dry specimens, points out that the relations of the lateral sinus to the surface are extremely uncertain, owing both to variations in the sinus curves and to irregularities in the bones. It begins opposite the external occipital protuberance in fifty per cent.; lower (by never more than ½ inch) in thirty-three per cent.; and higher in seventeen per cent. It does not run forward horizontally, but is distinctly arched. The bend of the sinus where it turns down at the asterion may vary, within wide limits, from a gentle to a very sharp curve. It then runs down in front of the post-mastoid margin, about ½ inch behind the meatus, and turns into the jugular foramen about ¼ inch below the level of the meatus floor. Occasionally the sinus is only $\frac{1}{12}$ inch from the surface.

Venous Outlets.—Possibly a couple should be added from Hédon. Small rami accompany the olfactory bundles through the cribriform plate of the ethmoid, of course connecting above with the vein of the olfactory bulb. "A vein leaves the aqueduct of Fallopius by the stylo-mastoid foramen to anastomose with the external jugular or post-auricular (Sperino). It joins, according to Blandin, a small dural ramus traversing the hiatus of Fallopius."

LYMPHATICS.—The previous recorded results of Rossbach and Sehrwald, regarding lymphatics in the brain-substance, are evidently discredited by Frommann (*Centbl. f. med. Wissc.*, 1888, pp. 881–2). As regards the hypophysis, Pisenti and Viola (*Ibid.*, 1890, pp. 451–2) believe that certain structures observed by them represent lymph-spaces. A cortical lymph-connective system has been studied by Bevan Lewis.

Little evidence of lymphatics in the myel is found by Kadyi. The perivascular spaces of His occur, but are likely of artificial origin. From the results of one injection he figures a net-work of voluminous canals running longitudinally beside the central canal, and that possibly represent a lymphatic system.

BRIDES-LES-BAINS. A watering-place in Savoy, near Moûtiers, France.

LOCATION.—Brides-les-Bains is situated in a beautiful valley, with picturesque surroundings, about 1,800 feet above the level of the sea. The climate is mild and invigorating. Facilities for interesting excursions are plentiful, although the place is somewhat difficult to reach.

ACCESS.—From Paris, by the Paris, Lyons & Mediterranean Railroad, *viâ* Chambéry, to Albertville; thence by stage in about three hours to Brides.

ANALYSIS.—One litre of the water contains:

	Gramme.
Chloride of magnesium	0.3071
Chloride of sodium	1.3601
Chloride of potassium	0.0670
Chloride of lithium	traces
Sulphate of soda	1.6113
Sulphate of magnesia	0.1941
Sulphate of lime	1.8200
Bicarbonate of lime	0.4380
Carbonate of iron	0.0112
Carbonic acid gas	0.0837

The temperature of the springs varies from 85° F. to 95° F.

INDICATIONS.—These waters are employed in a great variety of affections, such as obesity, liver complaints, abdominal plethora, gastralgia, constipation, vesical catarrh, affections of the prostate gland, hæmorrhoids, cerebral congestion, neuralgia, migraine, sterility, heart affections, diabetes, gravel, and diseases of women. It is said that the waters, if taken in the morning before breakfast, in doses of from one to three glasses per day, are tonic and aperient in their effect; in stronger doses, of from four to eight glasses per day, they become laxative and purgative. They have the advantage that they can be taken daily for a long period as a slight purgative without causing the irritation produced by other more active waters. Season, middle of May to end of September.

ACCOMMODATION.—The *Grand Hotel des Thermes* is modern and good. The *Établissement des Bains* is equipped with the usual appliances for bathing, sprays, etc. There is a small *Casino*, and mild amusements are provided. The place is quiet, and devoid of fashionable life. *Edmund C. Wendt.*

BRIGHT'S DISEASES OF THE KIDNEY, DELAFIELD'S CLASSIFICATION OF. Since pathologists have learned to distinguish the various diseases of the kidneys, formerly grouped under the one designation of Bright's disease, there has been an effort made to do away with this name as one that is indefinite and even misleading; yet so strong a hold has it acquired in the popular language that it is doubtful whether it will ever be supplanted. And, indeed, it is not necessary that it should cease to exist as a synonym for disease of the kidneys, for popular medical nosology knows as little of, as it cares for, pathological distinctions. It is, however, exceedingly desirable that the name should be dropped from scientific nomenclature, as its retention only serves to create confusion in the minds of students and to obscure the subject, at its best not a simple one, of the pathology of renal diseases. No modern writer would publish a work on pulmonary diseases and call it a treatise on "Consumption," yet it would be just as proper a term for diseases of the lungs as "Bright's disease" is for those of the kidney.

Writers have of late come to realize the inconvenience of this term, and have endeavored, after freeing themselves from the bondage of the name, to study renal diseases as distinct affections and group them scientifically, for a proper classification is essential to a clear comprehension of these different affections. The favorite method of grouping these diseases has usually been according to the part of the kidney involved, and we have therefore had such terms as "parenchymatous nephritis," "arterio-sclerosis," "glomerulo-nephritis," etc.—unsatisfactory enough, since the same inflammatory process may involve widely different parts of the organ, or the same parts may undergo varied and dissimilar pathological changes. A much better classification of diseases of the kidneys is one according to the nature of the morbid process, such an one as was proposed a few years ago by Professor Francis Delafield, of New York, which has commended itself to many pathologists and clinicians by reason of its simplicity and reasonableness, and which has already been adopted by many teachers and writers on renal diseases. A request had been made of the editor of this HANDBOOK that, in case a supplementary volume should be issued, place might there be given to an exposition of this mode of classification; and although Dr. Delafield was unable to prepare such an article, he very kindly placed his material at the disposal of the present writer, with permission to draw therefrom freely. He has also revised the article, so that the views here expressed may be regarded as his own. No attempt at originality of composition has been made, since the object of the writer was simply to give a *résumé*, as brief as might be consistent with clearness, of Dr. Delafield's published writings on the subject; and therefore the author's arrangement has been closely followed throughout, and in many places his very words have been borrowed. Any long extract taken bodily from his article in the *American Journal of the Medical Sciences* for October, 1891, has been marked by inverted commas.

There are three morbid processes concerned in the production of the various pathological changes in the kidneys formerly included under the term "Bright's disease," viz., congestion, degeneration, and inflammation. These three processes may be further divided according as they are acute or chronic, or as the inflammation is exudative simply, productive, suppurative, or tubercular. The Bright's diseases of the kidneys may therefore be classified as follows:

I. Congestion.	Acute.	
	Chronic.	
II. Degeneration.	Acute.	
	Chronic.	
III. Inflammation.	Acute exudative.	
	Acute productive or diffuse.	
	Chronic productive or diffuse.	With exudation.
		Without exudation.
	Suppurative.	
	Tubercular.	

I. CONGESTION.—*Acute congestion of the kidney* is a transitory condition caused by the ingestion of certain poisons, by traumatism, by operations, especially those on the bladder or urethra, by extirpation of one kidney, by over-exertion, or by taking cold.

There are no alterations in the renal tissues, the only change in the organ being the engorgement of the blood-vessels. Congestion may occur, however, not only in a normal kidney, but in one previously diseased, and in this case the lesions of the pre-existing disease will, of course, be present.

The urine is diminished in quantity, or, at times, even suppressed. It may contain albumin and casts, and occasionally blood: the specific gravity is, as a rule, unchanged. Usually constitutional symptoms are slight or absent, but in cases following surgical operations on the urethra or bladder, or extirpation of the other kidney, there may be considerable depression of the vital forces, ending in collapse, or a typhoid state with mild delirium may supervene. Acute renal congestion is usually recovered from, though it may in rare instances cause death. Repeated attacks, however, may lead finally to inflammation of the kidney.

The treatment consists in confinement to bed and in securing free action of the bowels and skin, the latter being accomplished by means of heat applied to the surface of the body.

Chronic congestion of the kidney is a secondary condition of engorgement of the renal vessels, following long continued interference with the venous circulation. It may be due to aortic or mitral disease, dilatation of the heart, excessive pleural effusions, pulmonary emphysema, or other obstructive diseases.

The kidneys are smooth, with non-adherent capsule, and are usually enlarged, though exceptionally they may remain of normal size; they are heavier than healthy kidneys and are also darker in color. The capillaries of the glomeruli are dilated and thickened; the veins of the pyramids are always, those of the cortex rarely, distended. There is commonly either swelling or flattening of the epithelium of the cortex tubes, although it occasionally appears to be unchanged.

The urine varies in quantity, but is usually diminished, the proportion of urea, however, being commonly increased. The specific gravity is ordinarily about 1.020 to 1.025, but may vary all the way from 1.010 to 1.035. There is little or no albumin, and casts are generally absent, though both may at times be found. The general symptoms are those of the primary disease, and the treatment is to be directed to this almost entirely.

The prognosis is grave, chiefly because of the tendency of chronic congestion to pass into chronic inflammation of the kidney.

II. DEGENERATION.—*Acute degeneration of the kidneys* is a secondary condition caused by the action of arsenic, mercury, or phosphorus, or of one of the toxines formed

in the body during the course of certain of the acute infectious diseases.

The lesions are confined to the renal epithelium, being most marked in that of the convoluted tubes. Here we find the epithelial cells simply swollen and irregular in outline, infiltrated with granular matter, disintegrated, containing hyaline masses, or in a state of coagulation necrosis. The kidneys are usually somewhat enlarged, with smooth surface and non-adherent capsule. When the degenerative process has been very rapid the blood-vessels are irritated and we then have congestion and exudation of serum, and thus a secondary exudative inflammation is added to the degeneration.

The urinary changes and general symptoms are in proportion to the extent of the degenerative process. In mild cases, such as occur with the acute infectious diseases, there are no symptoms beyond a moderate amount of albumin and some casts in the urine. But in severe cases, such as accompany yellow fever, or follow poisoning by arsenic, mercury, or phosphorus, albumin and casts are found in large quantities, white blood-cells are present, and the urine is scanty or even suppressed. The specific gravity of the urine is normal and there is no dropsy. In mild cases recovery is the rule, but in the more severe ones the kidney lesion is a direct menace to life.

There is no treatment for the degenerative changes, but if secondary exudative inflammation occurs the indication is to cause free movement of the bowels and diaphoresis.

Chronic degeneration of the kidneys, like the acute form, is a secondary process. It results from the same causes that may produce chronic congestion, or from alcoholism and vicious modes of life, or it may occur in the course of certain chronic diseases.

The degenerative changes are confined to the epithelium of the convoluted tubes which is swollen and the seat of fatty infiltration. When chronic congestion coexists the lesions of the glomeruli associated with that condition—dilatation and thickening of the capillaries—will be present. The kidneys are usually increased in size, though they may be normal or even smaller than in health; the surface is smooth. The pyramids are red, while the cortex may be whitish, yellow, or pink in color.

The urine may be increased in amount, scanty, or suppressed, the quantity varying in different cases and at different times in the same case. It frequently contains albumin and casts, but the specific gravity is not lowered and the relative proportion of urea is not decreased. The health of the patients is impaired; they fall away in flesh and strength, become anæmic, and finally pass into the typhoid state with delirium and stupor. Dropsy is not a symptom of chronic degeneration of the kidneys.

Treatment is usually ineffective, and the disease progresses steadily to a fatal termination, at best retarded only by the therapeutic measures employed. Of course, the exciting cause (alcoholism, irregular mode of life, etc.), should be removed or minimized as far as possible.

III. Inflammation.—The varieties of inflammation of the kidneys are:

Acute exudative nephritis.

Acute productive or diffuse nephritis.

Chronic productive or diffuse nephritis with exudation.

Chronic productive or diffuse nephritis without exudation.

Suppurative nephritis.

Tubercular nephritis.

Acute Exudative Nephritis.—This is one of the forms of kidney disease known as acute Bright's disease, acute parenchymatous, tubal, or desquamative nephritis, etc. It is "an acute inflammation of the kidney, characterized by congestion, exudation of the blood-plasma, an emigration of white blood-cells, and a diapedesis of red blood-cells from the vessels; to which may be added swelling or necrosis of the renal epithelium and changes in the glomeruli." The disease occurs as a primary inflammation or may complicate any of the acute infectious diseases or the puerperal state.

In mild cases there are no marked changes in the kidneys, the inflammatory products in the Malpighian bodies and tubes being discharged with the urine as fast as they are exuded. In more severe cases we find the red and white blood-cells, serum, and coagulable matter from the blood-plasma in the tubes, Malpighian bodies, and stroma, especially in the cortical portion. The kidneys are increased in size, smooth, and intensely congested. The epithelium of the cortex tubes is often flattened, as in the chronic congestion secondary to heart disease, or it may be swollen, or more rarely degenerated and detached. In some cases there is, in addition to the flattening of the cells, a uniform dilatation of all the convoluted tubes. Irregular masses, formed of coagulable matter from the blood-plasma, and hyaline casts are found in the tubes, the latter being more abundant in the straight tubes, the former in the convoluted ones. Red and white blood-cells may also be found in the tubes. When there is an excessive emigration of white cells these are usually found collected in foci in the cortical portion, and not uniformly distributed throughout the kidney.

In the glomeruli the capsular epithelium is swollen and there is also a swelling and growth of the cells covering the capillaries. In consequence of this latter change, although the outlines of the main divisions of the tufts may be visible, those of the capillaries are lost. In some cases the walls of the branches of the renal artery within the kidney are seen to be thickened, a result chiefly of the swelling of their muscle-cells.

The urine in mild cases of acute exudative nephritis is somewhat diminished in quantity, of normal or high specific gravity, and contains albumin and hyaline, granular, and epithelial casts in moderate numbers, and occasionally blood. The constitutional symptoms are often insignificant, consisting merely of a slight malaise, headache, and some aching in the back and limbs. The constitutional symptoms last from one to two weeks, the urinary changes from four to five.

In severe cases the changes in the urine are much more pronounced. The quantity is greatly reduced, or it may even be suppressed; the specific gravity is not lowered and may be raised; there is a large amount of albumin, casts are abundant, and epithelium and white and red blood-cells are often present. The amount of albumin and casts in the urine is usually, though not always, proportionate to the severity of the disease. The constitutional symptoms are also more marked. "A febrile movement with more or less prostration; stupor, headache, sleeplessness, restlessness, muscular twitchings, and general convulsions; dyspnœa, loss of appetite, nausea, and vomiting; a pulse of high tension with exaggerated heart-action, or hypertrophy of the left ventricle, dropsy, and anæmia—these may be called the characteristic symptoms of acute exudative nephritis. Of these symptoms a certain number—the fever, the prostration, the loss of appetite and nausea, the anæmia, the diminution in the quantity of urine, the albumin and casts in the urine—are such as would naturally accompany an acute inflammation of the kidney, and very often they are the only symptoms which do accompany it."

In a certain number of cases there are, in addition to these features, cerebral symptoms, dropsy, and changes in the heart and circulation. That these do not, in all cases at least, depend upon the diminished excretion of urine is evidenced by the fact that they are often absent in patients who are passing very little urine, and are often present in persons who are passing an abundance of urine of normal or high specific gravity. It is not improbable that they depend upon some morbid state, whether spasmodic or inflammatory, of the arteries and capillaries, whereby the passage of blood through them is impeded.

In cases in which there is an excessive production of pus-cells the symptoms not infrequently resemble very closely those of acute meningitis. "The invasion is sudden, with a high temperature and marked prostration. Restlessness, delirium, headache, and stupor are soon developed and continue throughout the disease. The patients lose flesh and strength and pass into the

typhoid state. Dropsy is slight or absent altogether. The urine is not so much diminished in quantity as one would expect; its specific gravity is not changed; albumin, casts, and red and white blood-cells are present in considerable quantities, but not always early in the disease, and may even be absent altogether."

This form occurs in children or adults as a sequel of diphtheria, measles, or scarlatina, or it may be a primary inflammation. It is uniformly fatal, but fortunately is not of very common occurrence.

The prime indication for treatment is to relieve the congestion of the kidneys, avoiding as a rule the use of diaphoretics or cathartics. This congestion is relieved partially and temporarily by means of the hot-air bath, dry or wet cups, hot applications to the lumbar region, or the exhibition of small doses of calomel or magnesium sulphate repeated at short intervals until the effect upon the bowels begins to be manifested. In order to prevent the cerebral symptoms the condition of the circulation should be closely watched. As soon as signs of increased tension of the arteries and labored action of the heart become evident, drugs to relieve this state should be given. These are aconite, nitro-glycerine, chloral hydrate, and opium; they should be given in small doses at regular intervals, but if the cerebral symptoms appear threatening then large doses by the rectum or subcutaneously are called for. The patients are to be kept in bed and put on a fluid (milk) diet until the disease begins to subside; then solid food may gradually replace the milk, and iron and oxygen will be indicated to overcome the anæmia.

Acute Productive or Diffuse Nephritis.—This is an acute exudative inflammation of the kidneys, to the lesions of which are superadded certain characteristic changes in the glomeruli and a growth of connective tissue in the stroma; its lesions are of a permanent character, and it is frequently associated with circulatory disturbances. It is very often met with as a primary disease, or it may complicate scarlatina, diphtheria, or the pregnant state.

The kidneys are smooth in the early stages of the disease, later roughened; the pyramids are red, and the cortex is thickened, white, mottled with yellow and red, or congested. The lesions are those of exudative nephritis with the addition of a growth of connective tissue in the stroma and of an increase in the capsule-cells of the Malpighian bodies. These additional changes, which are present from the first and are characteristic of this form of nephritis, are not uniformly distributed throughout the organ but are confined to strips or wedges following the line of the arteries. These wedges may be small, symmetrical, and few in number, or large, irregular, and numerous. Each wedge contains one or more arteries running up into the cortex and terminating in the tufts of the glomeruli; the walls of these arteries are thickened, there is a growth of cells upon and in the capillaries forming the tufts, and the corresponding Malpighian bodies show an excessive growth of the capsule-cells; in the stroma around these arteries, and parallel to them, is a growth of connective-tissue cells and basement substance. The growth of the cells lining the capsules is so great as to compress the tufts, the capillaries of which then become obliterated, and the glomeruli are finally changed into little balls of fibrous tissue. The new growth of connective tissue in the stroma leads to compression, and finally to atrophy, of the tubes around which it is formed.

The urine is scanty or suppressed, of high specific gravity, and contains a large amount of albumin, many casts, and red and white blood-cells. Later, the urine becomes more abundant, of lower specific gravity, and contains fewer casts and less albumin; or it may be that these less pronounced changes are present from the first. The general symptoms are headache, sleeplessness, muscular twitchings or general convulsions, anorexia, nausea and vomiting, dyspnœa, neuro-retinitis, diarrhœa, hypertrophy of the left ventricle of the heart, increased arterial tension, loss of flesh and strength, dropsy often extreme, and finally delirium, stupor, and coma. These symptoms vary according to the intensity of the morbid process, and there are often remissions simulating complete recovery. The disease is, however, a progressive one, and although life may be prolonged for a considerable period by appropriate treatment a fatal result comes sooner or later.

The treatment is essentially a climatic one, residence in a warm, dry, equable climate being most important. In some cases, during the early stages, a measure of relief may be obtained by the plan of treatment followed in acute exudative nephritis. For the dropsy, diuretics, diaphoretics, and cathartics are indicated; sometimes puncture of the skin or tapping of the serous cavities becomes necessary; but occasionally this condition refuses to yield to any mode of treatment. The arteries should be watched, as in acute exudative nephritis, and if they begin to show signs of increasing tension the appropriate remedies mentioned above are called for.

Chronic Productive or Diffuse Nephritis with Exudation.—This is a chronic inflammation attended with growth of connective tissue in the stroma, changes in the glomeruli, degeneration of the epithelium, exudation from the vessels, and sometimes changes in the walls of the arteries. The amount of exudation varies at different times, occasionally being so slight that little or no albumin is found in the urine. It should be remembered that the two forms of productive nephritis here described are essentially the same disease, differing only as there is or is not an exudation of serum from the blood-vessels in addition to the lesions of the productive inflammation. The disease may occur as a primary affection, may follow acute diffuse nephritis or chronic congestion or degeneration of the kidneys, or may complicate syphilis, tuberculosis of the lungs, bones, or joints, chronic endocarditis, or prolonged suppuration.

The kidneys are usually large, but may be small or of normal size, and are smooth, roughened, or nodular; the cortex is the seat of an extensive growth of connective tissue, its tubes being atrophied in some places and dilated in others; the straight tubes contain coagulated matter, cylinders, or blood; the renal epithelium is swollen or flattened, broken, granular, or fatty. "The glomeruli are changed in several different ways: 1. There is a growth of the capsule-cells in such numbers that they compress the tufts. The cells covering the capillaries are also increased in size and number. The capsule-cells may finally be changed into connective tissue and the tufts become atrophied. 2. The glomeruli are of large size, the cells covering the capillaries are increased in number so that the outlines of the capillaries are lost, but yet the capillaries are not compressed nor the glomeruli atrophied. 3. There is a growth of the cells which cover the capillaries and of the cells within them. Of the cells which cover the capillaries the cell-bodies become very large, the capillaries are compressed, and the glomeruli eventually become atrophied. 4. The walls of the capillary vessels become the seat of waxy degeneration, while the cells which cover them are increased in size and number. 5. If the nephritis follows chronic congestion, the capillaries are dilated and there is an increase in the size and number of the cells which cover the capillaries. The arteries remain unchanged, or they are the seat of obliterating endarteritis, or there is a symmetrical thickening of all the coats of the artery, or all the coats of the artery are thickened and converted into a uniform mass of dense connective tissue, or there is waxy degeneration of the walls of the artery."

During the exacerbations of the disease the urine is generally diminished in quantity or suppressed, but during the quiescent periods it may be normal; when the patients are doing badly, and often when they are dropsical, the quantity is greatly increased. The specific gravity slowly diminishes as the growth of connective tissue in the stroma of the cortex increases or when the capillaries of the glomeruli become the seat of waxy degeneration. Albumin and casts are present, usually in large quantity, but varying according to the activity of the inflammatory process in the kidney. Dropsy is of very constant occurrence in this form of renal disease,

being either continuous or coming and going from time to time. Other symptoms are marked anæmia, headache, sleeplessness, neuro-retinitis, cough, anorexia, nausea and vomiting, and dyspnœa. The latter when due to contraction of the arteries or to failure of the heart's action, is often the first thing that attracts attention to the kidney lesion; it comes on in attacks, especially at night and when the patient is lying down. The most constant symptoms are anæmia, dropsy, and albumin in the urine.

The course of the disease is almost infinite in its variety: "1. There are cases in which the symptoms are nearly continuous, the patients get steadily worse and die within one or two years. The anæmia, the dropsy, and the albumin are constantly present, and the patients die with dropsy or with chronic uræmia. 2. There are cases in which the anæmia, the dropsy, and the dyspnœa come on in attacks which last for weeks or months. Between the attacks the patients are comparatively well, often able to work, although the urine always contains albumin. 3. There are cases in which a number of years before death the patient has an attack of dropsy, etc., from which he apparently recovers and goes on able to work, but with urine of low specific gravity, which sometimes contains albumin. After an interval of many years comes the fatal attack, with all the characteristic symptoms. 4. There are cases which for years have no symptoms but pallor of the skin and urine of low specific gravity containing albumin. These patients often for a long time feel so well that they cannot understand that they have a serious disease. 5. There are cases in which the first symptom is the attack of spasmodic dyspnœa, the patients otherwise feeling well. It may be months or years before the other symptoms are developed. 6. There may be a history of chronic endocarditis lasting for years before the renal symptoms are developed. 7. There are cases which apparently recover from the disease."

The best results are obtained by sending these patients to a warm, dry climate where they can be much in the open air. As the urine contains a proportionately small amount of urea, its quantity must be maintained above the normal, if possible. The dyspnœa, convulsions, coma, and other symptoms due to arterial contraction will call for nitrite of amyl, nitro-glycerine, chloral hydrate, or opium.

Chronic Productive or Diffuse Nephritis without Exudation.—This form of nephritis is usually secondary to alcoholism, chronic lead-poisoning, gout, chronic congestion of the kidneys, hydronephrosis, or chronic pyelitis, or is brought about by the same conditions as those which cause emphysema, endocarditis, endarteritis, and cirrhosis of the liver.

The kidney is usually diminished in size, the two together often weighing only about one-half as much as one normal kidney. The surface is roughened or nodular, the cortex is thin and red or gray in color. In not a few cases there is no diminution in size, and there may even be an increase, but in all cases the capsule is adherent and the surface roughened. There is a progressive formation of new connective tissue in the cortex and pyramids, compressing and finally obliterating the tubes. The tubes not involved in the new growth become dilated, sometimes forming cysts of considerable size; the epithelium of these dilated tubes may be flattened, swollen, cuboidal, degenerated, or fatty. When the disease follows chronic congestion the glomeruli are large and there is a marked growth of cells covering the capillaries of the tufts; in other cases many of the tufts are compressed by the excessive growth of their cells and of those lining the capsules, and finally become converted into little fibrous balls. The capillaries of the glomeruli may also become the seat of waxy degeneration. The changes in the arteries are the same as those described as occurring in chronic nephritis with exudation.

Among the complicating lesions of this form of chronic nephritis we find hypertrophy of the heart, valvular disease, pulmonary emphysema, cirrhosis of the liver, pericarditis, bronchitis, or gastric catarrh.

The urine is usually increased in quantity, of a specific gravity of about 1.010, with little or no albumin or casts, except during exacerbations of the nephritis, and containing a diminished amount of urea. This is the typical urine of chronic non-exudative nephritis, but it is subject to important modifications. The specific gravity may remain constantly as high as 1.023, or it may fall almost to 1.000. In some cases several quarts of urine may be passed in the twenty-four hours, in others the secretion may amount to only a few ounces, or may even be suppressed entirely.

Dropsy is ordinarily absent except in cases complicated by chronic endocarditis or cirrhosis of the liver. Headache is sometimes a most distressing symptom, and neuralgic pains in various parts of the body are not uncommon. Sleeplessness is often complained of. Muscular twitchings and convulsions may appear early or late in the course of the nephritis. Hemiplegia may occur early and continue up to the end, or may disappear after a few hours or days; there may be several such attacks accompanied by aphasia or coma, or there may be periods of delirium with elevated temperature and contracted arteries—acute uræmia. Instead of these acute attacks the uræmic symptoms may come on gradually; the temperature is then usually low and the pulse rapid and feeble. Neuro-retinitis, bronchitis, emphysema, cardiac hypertrophy, valvular disease, chronic gastritis, and vomiting, one or more, are observed with more or less frequency in cases of chronic non-exudative nephritis.

"Dyspnœa is a very frequent symptom, often the first symptom noticed by the patient. It is a spasmodic dyspnœa coming on in attacks which last for minutes, hours, or days. It is regularly made worse by mental or bodily exertion, or by the recumbent position. It does not resemble pulmonary asthma. It is apparently due to the association of changes in the arteries and in the heart. With contraction of the arteries alone, or with a feeble heart alone, no dyspnœa may exist; but if the contraction of the arteries is so great that the hypertrophied and laboring heart is unable to overcome the obstruction, or if with the contracted arteries the heart becomes dilated or feeble, then the attacks of dyspnœa begin. At first the attacks are not severe and are of short duration, but if the mechanical conditions which cause them cannot be controlled they become longer and more distressing.

"Perhaps the most striking examples of this dyspnœa are in the patients in whom it is the first symptom of the nephritis. They are apt to be middle-aged or elderly men, often engaged in large financial or commercial enterprises. They profess that they feel quite well and that they can attend to their affairs perfectly, but that they are very much annoyed because early every morning they have an attack of asthma. In spite of their professions of good health, it is evident that they are pale and that they have dyspnœa on exertion. The heart is found to be enlarged, with or without a murmur; its action is either labored or feeble. The pulse is tense. The urine is of a specific gravity of 1.010 to 1.030; it contains no albumin, or only a trace. In the earlier stages of the disease this dyspnœa can be controlled, but later on it is more distressing and difficult to remedy."

While chronic diffuse nephritis, like the chronic productive inflammations of other organs, may be a serious and fatal disease, like them it may also exist as a lesion which does not interfere with general good health and a long life; and it is not at all uncommon to find evidences of the disease in persons who have died from other causes. The subjects of this lesion are, however, in constant peril, for though they may appear to be in fair health they are liable to succumb speedily to an attack of pneumonia or pericarditis, or to the shock of a severe injury.

"A very common form for the disease to take is that of attacks which are repeated a number of times, each attack worse than the preceding, and the general health more and more impaired between the attacks. During the attacks there are cerebral symptoms more or less severe—headache, sleeplessness, delirium, stupor, coma,

convulsions. Dyspnœa may be present or absent. The arteries are contracted, with a tense pulse. There is loss of appetite, nausea, and vomiting. The urine is of low specific gravity and usually contains albumin. Between the attacks the patients at first seem to be fairly well, but later they gradually lose flesh and strength. The urine between the attacks is of low specific gravity and contains little or no albumin. They finally die in one of the attacks, feeble and emaciated.

"In some of the patients spasmodic dyspnœa is the first symptom. This can often be controlled for months and years, and the patients then seem to be well. But after a time it is more difficult to manage, and other renal symptoms are added. In some cases there are no symptoms for a long time, so that persons apparently in good health are attacked without warning by convulsions, coma, delirium, or hemiplegia. They may die in the first attacks or live to go through subsequent ones. In some cases the only symptoms up to the time of the patient's death are gradual loss of flesh and strength and disturbance of digestion, the patient dying feeble and emaciated. These cases are hard to make out, unless the specific gravity of the urine is low and a little albumin is present. Otherwise there is nothing to draw attention to the kidneys as the cause of the illness. Loss of eyesight from nephritic neuro-retinitis may be the first symptom."

The treatment consists mainly in a regulation of the diet and mode of life, and in change of climate. The use of alcohol and tobacco should be stopped, and starches and sugars should be removed as far as possible from the dietary, the ingestion of fats on the other hand being encouraged. Residence in a climate that will permit of regular out-door exercise is advisable, and a change of scene and air occasionally is most desirable. The condition of the heart and arteries should be most carefully watched, and any signs of beginning tension should be at once met by the exhibition of the arterial dilators. A weak heart calls for cardiac stimulants. The use of opium is apparently safe when the arteries are contracted, but if they are not, a very little opium may prove fatal. In general convulsions or sudden coma, hypodermic injections of from one-eighth to one-quarter of a grain of morphine may be of decided benefit; and in cases of restlessness or wakefulness, with persistent arterial contraction, much relief may be obtained by an injection of one-eighth of a grain of morphine every three hours.

The other forms of inflammation of the kidneys, namely, suppurative and tubercular, do not call for consideration here, as they are not properly included under the designation of "Bright's diseases."

Thomas L. Stedman.

BROMOFORM (Terbromide of formyl, $CHBr_3$). In chemical composition it is analogous to chloroform, $CHCl_3$, and iodoform, CHI_3. It is formed by the action of brominated lime on alcohol in the same way that chloroform is made from chlorinated lime and alcohol. It is a bright clear liquid, specific gravity 2.9, taste sweet, without causing any irritation to the mucous membrane of the mouth; it has an ethereal odor, is almost insoluble in water, but is soluble in alcohol and ether. It is very volatile and is rapidly decomposed by light, bromine fumes being evolved which impart a pink color to the liquid.

Bromoform possesses anæsthetic properties, but in a less degree than chloroform, the period of excitement is less pronounced, and the anæsthesia is of shorter duration. It is also a powerful antiseptic.

A new application of this drug was brought to the notice of the profession in 1889 by Dr. Stepp, of Nuremberg, who advocated its use in whooping-cough. He claimed that the course of the disease was shortened in every instance, that the paroxysms were diminished in number and severity, and that complications were less frequent, and when present were benefited by the treatment. The dose he gave was as follows: From six months to one year, 2 minims three times a day; from one to two years, 3 minims; from two to three, 4 minims; from three to four, 5 minims; and from four to seven, 6 or 7 minims. In prescribing the remedy its high specific gravity must be remembered, one minim being equal to five drops. When administered internally no deleterious effects have been observed beyond an occasional sense of depression and lassitude. Two cases of poisoning have been recorded. In each instance the child had taken a large dose of the pure drug; it produced profound depression and collapse, from which both children recovered.

The drug is best given in a teaspoonful of water; it forms a "bead" in the water which is easily swallowed. It may be given in solution in water to which a small amount of alcohol is added, but should always be freshly prepared on account of its instability. How the drug acts is uncertain—whether as a specific, or on account of its germicidal properties, has not been determined. Dr. Stepp thinks bromine is excreted by the lungs after the drug has been decomposed in the system. The reports of others who have used it for this purpose corroborate the views of Dr. Stepp as to its efficacy in whooping-cough and its freedom from bad effects. *Beaumont Small.*

BROMOL (Tribromophenol). Is formed by adding bromine water to a solution of phenol. It is deposited in white crystals, taste is sweet and astringent, odor resembling bromine; it is nearly insoluble in water, soluble in alcohol, ether, oils, and glycerine.

It has been introduced as an antiseptic in the treatment of wounds, ulcers, etc. Applied in its pure state it has a slight caustic action and favors the removal of sloughs. As a dressing it is applied in solution in oil or as an ointment, one part in thirty. It has been used in diphtheria as a local application to disinfect the throat and remove the membrane.

When administered internally it is not acted on by the gastric secretions, and in the intestines is but slowly decomposed. Its action is therefore slow and prolonged. It is given in doses of 3 to 5 grains a day, and has proved of service as an intestinal antiseptic in cholera infantum and typhoid fever. For infants $\frac{1}{4}$ to $\frac{1}{3}$ grain may be given at each dose. *Beaumont Small.*

BUSSANG. A watering-place in the Vosges Mountains, France, used chiefly for "after-cures," although it boasts of several mineral springs.

Location.—The situation of Bussang in the Vosges Mountains, about two thousand feet above the level of the sea, is decidedly attractive, on account of the hills and fine forests in the immediate vicinity. The climate is, on the whole, bracing and tonic. The air is pure mountain air, as Bussang is right among the higher mountain peaks of the Vosges, at the foot of the Drumont and Rouge Gazon. The Moselle River rises near the principal hotel of the place. Near the German frontier is the *Col de Bussang*, "one of the most picturesque points of the entire Vosges." Mr. Wolff states ("The Watering-Places of the Vosges") that, as a watering-place, Bussang owes its reputation to three chalybeate springs, only two of which are at present worked. The principal is the *Source de Salmade*, which is used only for drinking. There is not very much bathing, but the baths are well organized and clean, and very refreshing. Massage is often combined with them. In fact it could not be spared for bathing, because in the busy time something like ten thousand litres is sometimes bottled in a day. The annual sale exceeds one million two hundred thousand bottles. The water is only slightly mineralized, containing about 1.5 gramme of solid matter in a litre. On the other hand, it is so strongly impregnated with carbonic acid, that carbonic acid intoxication has been known to result from too free use.

The Bussang water is not, like many other chalybeate springs, constipating, having, on the contrary, a mild aperient effect.

Access.—The village is reached from Paris, by way of Epinal, thence by stage or carriage.

Analysis.—Two springs are found, both almost iden-

tical in chemical composition. In one thousand parts there are found:

	Salmade. Parts.	Marie. Parts.
Silica	0.0641	0.0536
Oxide of iron	0.0059	0.0024
Red oxide of manganese	0.0019	0.0020
Alumina	0.0012	0.0011
Calcium	0.1519	0.1880
Magnesium	0.0506	0.0540
Carbonic acid (in combination)	0.7390	0.7277
Arsenic	0.0005	0.0004
Sulphuric acid	0.0904	0.0806
Chlorine	0.0507	0.0497
Sodium	0.3495	0.2890
Potassium	0.0346	0.0264
Lithium	0.0012	0.0010
Phosphoric acid / Boracic acid, fluorine	traces	traces
Total of solids	1.5414	1.4759
Free carbonic acid	2.8719	2.4934
Temperature	54° F.	50° F.

INDICATIONS.—Mr. Wolff is authority for the statements that, "the treatment at Bussang is not a very serious affair. There is no restrictive diet of any sort. You go to Bussang mainly to gather strength, and pick up the crumbs dropped at more exhausting watering-places. Durand-Fardel, the acknowledged authority on French waters, recommends Bussang water for dyspepsia, gastralgia, and chlorosis, and as a capital substitute for Vichy in the case of people who cannot stand the strongly mineralized spring of that place. Dr. Onimus, the doctor of the spa, also speaks of excellent results obtained through its contracting action upon the bladder. Constantin James places it, for its effects, midway between chalybeate and alkaline springs. Its main use is as what the French call a *reconstituant*, and for this effect there could not be a happier combination of water and high position than is actually found at Bussang."

ACCOMMODATION.—The village hotels are primitive. There is a good new *Hôtel des Sources*, in close proximity to the bathing establishments. There are no particular amusements, and the place is decidedly "quiet."

Edmund C. Wendt.

BUXTON. One of the most popular thermal stations in England.

LOCATION.—Buxton is pleasantly situated in a picturesque part of Derbyshire, about thirty miles northwest of Derby. It is nine hundred feet above sea-level, and surrounded at some distance by hills of moderate elevation. The mineral springs are the most noted in England, and the town resembles in its newer sections the fashionable Continental spas. The air is pure and bracing, but like other English resorts, the place is visited by too many damp and rainy days to be always enjoyable. The springs were known to the Romans. There are many public and private baths, and there is a large public hospital, the Devonshire Hospital, where the waters are much used. Season, June to October.

ACCESS.—Buxton is reached from London (St. Pancras Station) by the Midland Railroad in four hours.

ANALYSIS.—The principal ingredients of the Buxton waters are, carbonate of lime, carbonate of magnesia, chloride of sodium, chloride of calcium, silica, all in relatively small proportion. Indeed the efficacy of the springs is scarcely due to their mineralization, but almost wholly to systematic external use and the diluent action of pure water. The temperature of the springs varies from 60° to 82° F., and the water contains a large amount of nitrogen.

There is also a chalybeate spring at Buxton, known as St. Anne's Well, but it is only sparingly used.

INDICATIONS.—The Buxton waters are employed almost exclusively in gouty, rheumatic, or lithæmic conditions. But dyspeptics, and sufferers from genito-urinary troubles are also sent there. Patients with hysterical palsies also go to Buxton in large numbers.

ACCOMMODATION. — The Buxton thermal establishments are good, though less perfect in their appliances and comforts than many Continental places. The hotels are clean and typically English, which means that they are inferior to many French, German, and Swiss ones in point of food and furnishing. *Edmund C. Wendt.*

CACTUS GRANDIFLORUS. This is the well-known plant, night-blooming cereus, of the order Cactaceæ. A native of Jamaica and the West Indies. It has been introduced as a cardiac tonic, and is said to have certain advantages over digitalis. A fluid extract and a tincture are prepared. The dose of the former is from 1 to 5 minims. The tincture is made of the strength of one part in six of alcohol, and the dose is 5 to 10 minims, which may be increased to 30 minims. It has been recommended to have the preparations made from the fresh plant. An alkaloid, *cactina*, has been separated which possesses all the active properties of the plant.

The advantage that cactus grandiflorus has over digitalis is its continuous stimulating action on the heart. Digitalis, it has been shown, acts first on the pneumogastric nerve, stimulating the heart and increasing the blood-pressure; this is followed by a relaxing of the vaso-motor vessels and depression of the vagus. The new drug, on the other hand, is supposed to be free from this secondary effect, and may be given for a prolonged period without producing exhaustion. It is likely to prove useful in asthenic rather than sthenic cardiac troubles.

It is supposed to act on the medullary centre and through the pneumogastric and sympathetic on the heart. It is a stimulating tonic and invigorates the cardiac plexus, and promotes the nutrition of the heart. No ill effects have been observed from its use. It has been employed as a substitute for digitalis in cardiac dropsy and acted most favorably, its use being continued for some time, supporting the heart and circulation; and in some cases in which repeated tapping had been required, this procedure was found to be no longer necessary.

Its greatest use, however, appears to be in functional and neurotic affections of the heart, palpitation, irregularity, fluttering, slow or rapid action, and other conditions arising from debility, worry, dyspepsia, the excessive use of tobacco or tea, and such other conditions, where no organic disease exists. It has also been used with success in pseudo-angina pectoris and in exophthalmic goître, relieving the sense of oppression and pain, and producing a more regular action of the heart.

Beaumont Small.

CÆCUM AND APPENDIX, DISEASES OF. Since the first edition of this article our knowledge of diseases of the cæcum and appendix has been increased greatly by observations made during the course of operations undertaken for relief of inflammatory conditions. It is recognized that more than ninety per cent. of all inflammatory conditions in the right iliac fossa commence in the appendix, and in a large number of these the starting-point is an aggregation of probably dried fæces within the appendix; hence the term appendicitis has replaced the various other terms applied to inflammations in that region—typhlitis, perityphlitis, paratyphlitis. As our pathological information increases, unquestionably other terms will be coined, but, for the present, appendicitis is a good working word and suggests the origin of the trouble. Inflammation in the right iliac fossa occurs under many forms and much the larger proportion do not fall under the care of the surgeon, being curable by medical means alone.

On the other hand, a certain number require prompt and immediate attention from the surgeon, and the question of diagnosis is one of paramount importance. It is not very difficult to lay down rules as to what cases should be subjected to such and such treatment, but when face to face with the patient it may be safely said that with our present knowledge an accurate diagnosis is not obtainable. Much better are we now able to recognize the condition of affairs about the appendix than a very few years ago, but much still has to be done, and no doubt the observations made during life and the conditions recognized during operations are the factors upon which we shall have to depend for future improvement.

Increase of knowledge, based on clinical observation

during the past few years, justifies the opinion that appendicitis occurs in females nearly as often as in males, and from very early childhood to middle life.

The starting-point usually is the appendix, in exceptional cases only is it the cæcum, and then probably tuberculosis exists. The inflammation appears to begin in the lining membrane of the appendix, and may be catarrhal in character, without obvious cause; but a concretion is found in very many cases, and this is probably the foreign body spoken of under the name of "prune-stone, date-seed, coffee-berry," etc., which have been occasionally referred to in the medical periodicals of the day. It is likely that a piece of fæces has entered the appendix and, remaining for a certain time, has become dried more or less by absorption of the watery constituents; or perhaps retained by a fold of mucous membrane it has become embedded and hardened by the process already mentioned. Certain it is that a foreign body has been found again and again to be present in cases of appendicitis, more often than could possibly happen by accident; hence, a place in the causation of the disease is to be given to the more or less large mass of hard substance—probably fecal—so often present. The coats of the intestine may give way gradually until the actual rupture takes place, or the thinning of the wall of the bowel may occur with successive attacks of inflammation. It would be expected, as the intestinal wall becomes thinner, that adhesions between adjacent coils of bowel would take place, and that this does happen is testified to by the many cases of circumscribed suppuration about the appendix; but occasionally the failure of adhesions to take place permits general septic peritonitis to occur. Just why an inflammation should take place in the appendix without the presence of the foreign body as an exciting cause, we are unable to say, but so many cases are met with at post-mortem inspection which give evidences of cured inflammation about the appendix that the fact has to be admitted. As the appendix is probably the relic of a large cæcum existing formerly, it would be proper to consider this part of the intestine as an organ not capable of resisting disease to the same extent as do the other portions of the bowel; hence it would be the place of least resistance. The formation of pus is thus to be looked upon as an intra-peritoneal, not an extra-peritoneal formation. It has been my fortune, on one occasion, to be able to lift such an abscess, circumscribed by coils of the bowel, out through the abdominal incision and open it outside of the body. The point where the inflammation begins may be at the apex or at the base of the appendix, or between the two. When it is situated at the base of the appendix, the cæcum is also found to be inflamed, but so soon as the pus forms it is not a matter of much consequence what is the extent or the exact locality of the abscess, for everything is tied up together. It may of course happen that the peritoneal adhesions are very dense, and the pus may make its way into the connective tissue about the cæcum or other organ.

The onset of an attack may be either sudden or gradual. In the latter case there will have been attacks of bowel disturbance, constipation and diarrhœa, with abdominal cramps, for a certain period; not enough, perhaps, to have caused the patient to seek the services of a physician, but sufficient to have caused a certain anxiety on his, the patient's, part. Perhaps the physician may have been consulted, but if so, it has been for indigestion or some slight disorder. In a certain number of cases the onset of the disease is acute, pulse and temperature both rise, acute pain is present and is referred to the right iliac fossa, although possibly elsewhere. The patient may be cognizant of a certain stoppage in the bowel, as he describes it, and he becomes anxious. Pain, while generally referred to the locality mentioned, is not always so by any means. Sometimes the epigastric region is indicated, sometimes the navel, and sometimes a corresponding point on the left side of the abdomen. In one or two of my cases the pain has been referred to the right loin, not far from the spine. On one occasion, where the pain was referred to the epigastric region, it could be mitigated or often made to disappear by pressure of the hand on the right groin. The place of greatest sensitiveness has been referred to a point inside the right iliac spine, about two inches distant on a line drawn from the anterior superior spinous process to the navel, which point is supposed to be over the base of the appendix. I have found this to be the case, and while pressure in that region causes pain I have not been able to locate it so accurately as has been done by others. Rigidity of the abdominal muscles is very constant, and more often seen on the right than the left side, but it sometimes requires pressure to induce it. Temperature shown by the thermometer is generally not high, unless in the late stage of the trouble. Purulent septic peritonitis may exist with subnormal surface or mouth temperature. Rectal temperature is higher by several degrees than mouth or surface temperature. I attach much less weight, in forming my opinion of the patient's condition, to the amount of fever than I do to the condition as shown by the pulse. This latter is a vastly better index. Constipation is often present, and may be so marked as to be mistaken for obstruction; indeed a certain number of cases have been treated for obstruction. Doubtless the cause is paralysis of the intestinal wall in consequence of the presence of the inflammation, but a change from constipation to diarrhœa, brought about by medicine, is seen in cases of abscess rather than in diffuse peritonitis. When, therefore, frequent passages are induced by medicines following an apparent obstruction, I am inclined to think that my patient has escaped a general septic peritonitis. Tympanites, occurring early during an attack, is not favorable; continuing constantly, it is not a favorable symptom, and if associated with constipation it indicates loss of power in the intestinal wall. Shock is marked when perforation takes place, otherwise it is not a prominent symptom. Vomiting of the contents of the stomach, and subsequently of the contents of the upper part of the small intestine, suggests peritoneal involvement; in general peritonitis the material vomited is apt to resemble finely cut spinach in color. The color changes to brown as the scene closes, and is apt to be very profuse in the last hours of life. Œdema of the abdominal wall is met with where an abscess is immediately adjacent. Tumor in the right iliac fossa is not found at the commencement of the attack, but may appear shortly. At first it is probably due to an adhesion of the intestines around the focus of primary inflammation or the swollen appendix. Later, as pus forms, the tumor naturally becomes larger if walled in by adhesions. Where the inflammation is not shut off by adhesion from the rest of the peritoneal cavity the tumor is wanting; such cases are rapidly fatal and call for active interference at an early day. The rigor and chill may occur with the commencement of the inflammation, or later, but they are rarely wanting at one time or another. Free extension of the thigh often causes pain. Digital examination by the rectum is occasionally useful and should not be neglected, but will be of especial use when the intra-peritoneal tumor has acquired a certain volume or where it extends downward toward the rectum. An appendix which hangs over the brim of the pelvis, if inflamed, may be recognized early in the disease by the rectal touch. In cases where inflammation extends into the pelvis, involvement of the peritoneal covering of the bladder may occur; hence, frequency in passing water is a symptom of value. It is usually accompanied by scalding along the urethra, with pain at the meatus, and spasm of the bladder, sometimes very severe. Fluctuation is not to be expected, although occasionally met with; its presence indicates a large amount of pus situated superficially, and certainly is wanting in the early stage of the trouble. Its presence should not be expected, either for diagnosis or treatment. Percussion is rarely dull, for often, if pus is present, it will either be overlaid by intestine or so closely in relation therewith that dulness is wanting, and pus may be under the abdominal wall so that it can be cut into without difficulty, yet a tympanitic note will exist. The countenance is apt to indicate the gravity of the trouble moderately well; dark circles about the eyes are not a hopeful sign, and apparent receding of the eyes within the sockets suggests ex-

treme illness. The introduction of the needle of a hypodermic syringe into the affected area, with a view to the discovery of pus, is most unwise. I believe incision to be safer. There is no knowing just what the needle may reveal, and it may conceal much.

A large number of cases recover from appendicitis, usually the catarrhal form, and they do not fall under the notice of the surgeon. A few days' rest and gentle purgation, and the patient recovers. Some cases, on the other hand, are not followed by perforation, but they induce suppuration within the peritoneal cavity, which becomes promptly circumscribed and walled in by adhesions of adjacent intestinal loops, thus shutting off the general cavity from infection. In another class of cases perforation does take place, but this also is walled in as in the preceding class. Finally, another class exists in which perforation occurs, but without the walling in just described; whereupon a general infection of the peritoneum follows. These latter cases die, with few exceptions. The difficulty which presents itself to the physician is the recognition of those cases which will be circumscribed and those which will not, and it is to be regretted that at present it is impossible to certainly differentiate between them. They are apt to be alike in commencement, for a certain number of hours, at all events, and yet early operation will prevent the rupture and general peritonitis in the one class, while in the other surgical interference is not needed.

The term "early" used here is not intended to apply to the length of time that the attack has lasted. It does refer to the pathological condition, and refers especially to perforation, so that an operation undertaken soon after the commencement of the pathological condition which would eventuate in rupture, may be in the one case a few hours and in the other case several days after the commencement of the illness. The term "early," then, as ordinarily used, is a misnomer in my opinion.

Probably a position of armed neutrality is the proper one for the physician to assume, and when I say physician, I mean that the attending physician, if not a surgeon, should promptly call in a surgeon, and together the two should conduct the case. It is right that the surgeon should see the case from the start, but equally he should know how to withhold his hand, and not think, because he is called in, that he should at once operate. In no class of cases is good judgment of more value to the patient, and equally may it be said that in no class of cases is a correct judgment more difficult to form. Perforation usually takes place, if it takes place at all, in the first three or four days after the onset of the disease; hence the necessity for forestalling a fatal rupture is apparent. Where the abscess is circumscribed, the operator has time to open and drain, and general peritonitis is then very rare. Where perforation takes place without formation of adhesions, fatal peritonitis results. Such a condition should be prevented by prompt operation and removal of the appendix, which is the starting-point of the trouble. Only careful and continuous observation will enable the surgeon to recognize the necessity for interference. The pulse progressively increasing in frequency, the temperature rising or remaining high, acute pain on pressure in the right fossa, perhaps near the point already referred to, constipation present, with or without a swelling in the right fossa, rigid right rectus—these are the indications which may be held to call for an operation. The pulse not frequent, diminishing pain, moderate temperature, absence of tympanites, will justify the surgeon in waiting. The incision, when made, should be as long as may be necessary to give free access to the seat of disease, and the centre of the incision should fall on a line drawn from the navel to the anterior superior spinous process, about two inches from the bone. The peritoneal cavity should be opened to the same extent as the skin incision; unless the operator finds adhesions closing in the seat of inflammation, these should not be disturbed. The coils of bowel are to be pressed aside, the seat of inflammation found, and the pus evacuated. In circumscribed cases the adhesions should not be ruptured, but the appendix should be sought for and explored by touch and sight, if possible; if a concretion be present it should be removed and the appendix tied off, but not if by such action the general peritoneal cavity is likely to be opened. On the other hand, where no abscess exists and the appendix is the cause of the trouble, with or without contained concretions, the appendix is to be tied off by a ligature applied close to the cæcum. It is well to apply pure carbolic acid to the stump. This removes the cause of the trouble, and is an operation essentially different from the one referred to first. The wound is to be lightly filled with gauze which will be removed later, and healing by granulation allowed. Whether it is necessary or not to flush the general peritoneal cavity, will depend on the condition found. If suspicion of septic peritonitis exists it would probably be wise to do it. I do not think that it is necessary to remove the appendix in all cases, especially in cases where pus is circumscribed. The appendix in these cases is generally closed by adhesive inflammation, and I believe that much injury is done by indiscriminate search for this organ by rupturing adhesions, rather than by leaving them alone after the pus is evacuated, and permitting the cavity to heal by granulation. A perforated appendix heals without difficulty.

Opium I give rarely; it produces quiet on the part of the patient without arresting the progress of the inflammation; hence it masks symptoms which might necessitate an operation. On the other hand, saline purgatives I use freely, for reasons already stated, hoping to produce frequent evacuations from the bowels. Irritants or blisters to the abdominal wall have yielded, in my hands, no good results; more comfort follows the application of ice over the seat of inflammation.

Recurrent Appendicitis.—Appendicitis is met with occasionally as a recurrent trouble, and the question will be raised as to treatment. It is impossible to say, first of all, whether the attacks are dangerous or not, or whether a person having escaped one, the next attack may not be fatal. Such a disease generally calls for operation, the chosen time being the period between two attacks. The operation which should be done will be the uncovering and the removal of the appendix, in which the cause of the trouble exists. Undoubtedly such an operation carries with it a certain amount of danger, but probably not so much as would be present with an attack of appendicitis. Generally speaking, it may be said that where attacks of appendicitis recur with sufficient severity to cause much inconvenience, or imperil existence, then an operation is proper. On the other hand, slight attacks of cramp in the right fossa, unless there be some special indication, may be considered as a trouble which will cease without operative interference.

CAFFEINE. This alkaloid and its salts continue to be used for their stimulant and diuretic properties, and numerous communications indicate that it still proves of service in headaches, migraine, neuralgia, cardiac debility, and dropsy due to heart disease. It has latterly been advocated as a cardiac stimulant and restorative in the prostration and debility of typhoid fever, pneumonia, and post-partum hemorrhage. Two to four grains are advised to be given every four hours; in the latter condition, where a more prompt action is required, eight or ten grains may be administered hypodermically. It also has been found that its diuretic properties are increased and its general effect improved by combining with paraldehyd. Four or eight grains are to be used with thirty or forty-five minims of paraldehyd. Its diuretic action has been clearly shown to be due to a direct effect on the secreting tissue of the kidney, which, in addition to its action on the circulation, makes it a most effective and rapid diuretic. It differs from digitalis by this promptness of action. The influence of digitalis is not exerted until the blood-pressure has been raised and then succeeded by a relaxing of the renal vessels, which may not be effected for some days. The influence of caffeine is much more rapid, and may be noticed in a few hours.

Notwithstanding the extent to which it has been em-

ployed and the success attending its use, our knowledge regarding the *modus operandi* of caffeine is meagre and unsatisfactory. To a very great extent it has been of an empirical character, and not based on any very precise data. Researches during the past few years have thrown some light on its effects on the circulation and metabolism, and on the ultimate effects produced by its administration, and as a result our views regarding its action on the heart must be greatly changed, and its continued use in cardiac debility must be guarded and cautious. In 1890 Professor Germain Sée presented to the French Academy of Medicine the result of some experiments made by himself and M. Lapicque, to verify its reputed restorative and stimulating properties. These experiments, which extended over a period of twelve months, demonstrated very clearly its influence over the muscular system. He found that untrained men could perform long journeys and enter races without enduring fatigue or exhibiting any sign of distress. By the means of registering apparatus it was found that there was no alteration in the respiratory or circulatory rhythm, and numerous other facts proved that the use of caffeine enabled a trained or untrained person to perform muscular efforts that otherwise could not be undertaken. He concludes that small quantities, amounting to about ten grains in the day, may with advantage be given to soldiers on the march, or where any muscular effort is required, as it prevents shortness of breath and palpitation and supplies vigor and endurance. He considers that the caffeine acts on the cerebro-spinal centres, stimulating the motor nerves, favoring the combustion of nitrogenous elements, and promoting the excretion of carbonic acid and other products of tissue change. By this means strength is furnished, not by supplying anything new, but at the expense of the individual by enabling him to draw upon the energy that is latent in the system. In no sense does it replace food, and unless this drain upon the system is replaced an unfavorable result follows. Professor Sée likens its special stimulating power to that possessed by food which will prove a source of stimulation by its presence before it is in any way acted upon by the gastric juices. As to its action on the heart and blood-vessels, he considers that but little is known and cannot be properly understood until xanthin and its series of products has been studied, caffeine being chemically tri-methyl-xanthin.

The experiments of Dr. Reichert, of the University of Pennsylvania, on animals, form a valuble corollary to the views of Professor Sée, and add much to our knowledge of the action of caffeine on the heart and blood-vessels. Reichert's experiments were instituted because he considered that the drug was but little understood, and because the very prevalent idea that it was a beneficial cardiac stimulant, was based on experiments that were incomplete and open to serious objections. He benefited by the experience of others and avoided their sources of error, with very satisfactory and important results. In a series of experiments on the production of heat during the administration of caffeine, he shows conclusively that the amount of heat produced and the amount dissipated are augmented, and in consequence with the increased energy a corresponding drain on the system takes place. Its reputed stimulating properties he considers to depend on a general excitation of the cerebral centres, the effect of which he likens to the energy and force exhibited by persons when the subject of a fright, hysteria, or mania, during the influence of which unusual deeds of endurance and strength are performed, but at the expense of the system.

His experiments to determine the condition of the blood-pressure and the effect on the heart were very complete. Solutions of caffeine were introduced into the external jugular vein and also hypodermically; the pressure was recorded by a manometer in the carotid artery and the action of the pulse carefully observed. The effect was noted in dogs in their normal state, in others with the pneumogastrics severed to cut off the influence of the inhibitory centres, and in a third series in which the upper spinal cord was cut to determine the influence of the accelerator centres. The results of his observations are given in the following conclusions:

1. The pulse-rate may be diminished during the first and last stages of the poisoning, but is generally decidedly increased. During the first stage the diminution is due to a stimulation of the cardio-inhibitory centres in the medulla oblongata and heart, and during the last stages to a direct depression of the heart. The increase in the pulse-rate is due to a depression or paralysis of the above cardio-inhibitory centres.

2. Arterial pressure during the first stages of poisoning is generally unaffected or diminished, but occasionally a trifling increase is noted. The increase is due to a direct stimulant action upon the blood-vessel walls, increasing vascular tension. The diminution is due chiefly to a direct depression of the heart, and to some extent, doubtless, to a secondary paralysant action on the vessel-walls.

3. The acceleration of the heart-beats may be accompanied by no appreciable alteration in blood-pressure, but generally by a more or less decided diminution, which is dependent upon cardiac depression.

4. Caffeine diminishes the heart's efficiency for work, arrests it in diastole, sometimes induces sudden paralysis, and is therefore a cardiac depressant.

5. The asserted stimulant action upon the circulation is doubtless subjective and dependent upon an excitation of the cerebral centres. *Beaumont Small.*

CAMBO. A popular thermal station in the department of Basses Pyrénées, France.

Location.—Cambo is charmingly situated, not far from fashionable Biarritz, to which fact, as well as to its mineral springs and a well-managed bathing establishment, it owes the growing favor with which it is regarded. Although it is open all the year round, there are really two seasons, one from April to June, and the other from September to the latter part of October. The climate is soothing. Cambo is 200 feet above sea-level.

Access.—By railroad to Bordeaux, and *viâ* Dax to Bayonne. Three hours by stage from Bayonne.

Analysis.—There is an alkaline sulphur spring, having a temperature of 80° F., with the following chief ingredients: Sulphate of lime, sulphate of magnesia, sulphate of sodium, small quantities of arsenic and lithium. It is rich in free carbonic acid. There is also a cold chalybeate spring.

Indications.—Cutaneous affections, lithæmia, chronic diseases of the organs of respiration, catarrhal affections of the alimentary canal, scrofula, and anæmic states are chiefly treated at Cambo. It is a good place also for convalescents from acute diseases, there being pleasant and sheltered promenades and fine scenery.

Accommodation.—The Grand Hôtel d'Angleterre, and the Hôtel de Paris are good hotels. The thermal establishment has the usual appliances.

Edmund C. Wendt.

CAMPHORIC ACID, $C_8H_{14}(COOH)_2$, is formed by the oxidation of camphor, and may be prepared by heating camphor with nitric acid. The acid forms in small colorless needles or plates, odor faintly aromatic, taste acid and bitter, very sparingly soluble in cold water, more soluble in hot, soluble in alcohol and ether. Ten per cent. of alcohol added to hot aqueous solution prevents it from being deposited on cooling. This acid has long been known, but it is only during the last two years that its therapeutic properties have been utilized. Its latest use is for the treatment of diseases of the respiratory tract and as a preventive of night-sweats.

For the latter purpose it promises to be one of the most valuable additions to our materia medica. Compared with atropine its effect is more certain and more prolonged, while it does not produce the difficulty in swallowing, dryness of the pharynx, disturbed sleep, and vertigo, which often accompany the use of the latter drug. Compared with atropine its mode of action differs, as its beneficial effect is thought to be due to its power of de-

stroying the ptomaïnes in the blood which cause this distressing symptom.

The dose as an anhydriotic is thirty grains at bedtime, or fifteen grains during the afternoon and the same dose repeated at bedtime. The action is not rapid, and in some instances no effect has been noticed until the following day. The effect of a single dose often continues for several days. The reports of cases treated show beneficial results in a great majority of them; it does not in any way interfere with the appetite or digestion, and in most instances a quiet sleep followed its use. As the taste is somewhat disagreeable, it is best administered in wafers or capsules. In diseases of the mucous membrane of the respiratory tract, camphoric acid is used by applying locally and as a spray. In acute coryza, pharyngitis, and laryngitis a half to one per cent. solution may be used every three hours, or tampons saturated in the solution may be introduced into the nasal cavities; in ulcerated throat, a solution of two to six per cent. may be applied. This drug has no corrosive action; it possesses antiseptic properties and produces contraction of the blood-vessels of the mucous membrane. Internally, it is also used for intestinal diarrhœa of a catarrhal character, and where intestinal antisepsis is desired, the dose is from five to ten or fifteen grains. It is excreted by the kidneys and renders the urine clear and acid in two or three hours.

In cystitis, when the urine is alkaline, it has proved of benefit. In this condition it is also used as a wash in a half of one per cent. solution. The bladder is to be irrigated twice a day, about an ounce of the solution being left behind. *Beaumont Small.*

CANADA, CLIMATE OF.* The climate of a country must ever be considered of the greatest moment to human welfare. What is climate? It is not obliquity of the sphere with respect to the horizon, from which results the inequality of day and night; it is not the imaginary circles parallel to the equator; nor is it the weather peculiar to a given country; nor its heat, nor its cold, nor its dryness, nor its moisture; nor the course or character of the winds; nor the changes of the seasons; but all these combined, together with its salubrity and insalubrity. It is, in a word, according to Humboldt, "the changes in the atmosphere which sensibly affect our organs, as temperature, humidity, variation in the barometrical pressure, the calm state of the air, or the action of opposite winds, the amount of elastic tension, the purity of the atmosphere, or its mixture with more or less noxious gaseous exhalations, the degree of ordinary transparency and clearness of the sky, the organic development of plants, and the ripening of fruits." But to these must be added the feelings and mental and social condition of man as affecting and modifying the influence of climate everywhere. Distance from the equator and height above the level of the sea are not therefore the only conditions comprised in the function of climate.

Climate is influenced markedly by the physical geography of a country. The Registrar-General for Scotland, in explanation of certain phenomena, the causes of which are not quite obvious to the reader, generally describes Scotland to be of extremely irregular figure, and attributes the disturbance of the mortality tables to that cause. Writers generally admit that there is neither conceit nor irrelevancy in the matter. Climate affects our stature, our strength, and complexion; causes and cures disease; prolongs or shortens life. Its influence may be seen in the great variety of races which inhabit the earth, presenting every tinge and hue of complexion, from the pale white to the ebony black; and in the vast variety of intermediate races—all descended from one common parent,—the theories of the pluralists to the contrary notwithstanding.

There must be added a third element, which affects man in health and disease, and which influences the tables of mortality, viz., the ordinary condition of wealth and comfort, or the reverse.

Before entering upon the subject of the paper it may be well to state the conviction that the influence of climate upon man and upon the brute creation is marked, —more marked, indeed, upon the lower animals than upon man,—for the latter is not so completely exposed to the influence of climate as are the former. A few generations will so change many animals as to make them scarcely recognizable; while man requires a period so great that some are disposed to doubt that any amount of intra- or extra-tropical influence can convert a white into a black man, or a negro into an Esquimau.

As has been said, climate generally has an intimate relationship to the physical geography of a country, and the climate of Canada is not an exception. Its vast extent of country, from the Atlantic in the east to the Pacific in the west, and from the Arctic Ocean, Baffin's Bay, and Davis's Strait on the north and northeast, to the boundary line, forty-fifth degree, and the great chain of lakes in the south and southeast, would necessarily give it a varied climate.

Canada occupies a great portion of what has been styled the Interior Valley of North America—a valley which may be said to occupy six million square miles, beginning with the tropics and terminating within the Polar Circle, traversing the continent from north to south and passing through the entire northern zone. This valley rests upon, and is indented by, the Gulf of Mexico on the one side, and by Hudson's Bay on the other; a valley which is protected from the Pacific Ocean on the west by the Rocky Mountains—mountains varying from ten to fourteen thousand feet in height, which greatly modify the distribution of rain, the direction of winds, and in many ways influence the climate. The Appalachian chain of mountains—a chain interrupted only at the forty-second degree of latitude by the Great Lakes and the St. Lawrence—bounds this valley in the east. The distribution of these chains of mountains permits a more direct oceanic influence on the Atlantic or eastern side than on the western or Pacific side.

The enormous fresh-water lakes within that valley influence most materially the climate of Canada. The basin of the St. Lawrence alone has an area of upward of half a million square miles, and contains lakes having an area of one hundred and thirty thousand square miles. The St. Lawrence basin is hemmed in on both sides by mountain ranges: the Laurentide on the north, the mountains of Notre Dame on the south. The latter form the Vermont Mountains, mountains which exert so potent an influence upon the climate of both the United States and Canada. The ranges of these mountains vary in altitude from a few feet to four thousand feet above the sea. At different heights along these mountain ranges numerous watersheds are met with, in addition to those in the basins already alluded to—the Lacustrian chain, which begins in a cul-de-sac formed by the Arctic Ocean and the Rocky Mountains. So great in number are these fresh-water lakes that many of them have not yet received names. Some of these lesser watersheds have not been fully explored, yet their genial influence upon the climate of the country is admitted. The low altitude of Canada is favorable to its climate and to its vegetation. Were the plateaus on the north coast much elevated, vegetation would be confined to the mosses, and animal life to a few hardy, thick-furred animals. But all the long gentle slopes descend toward the Atlantic and the Frozen Ocean; while all the short and rapid slopes, or counter-slopes, are directed toward the Pacific. The land in Canada ascends in a series of plateaus as we approach the interior, and we reach the height of tableland, as it is termed, on the south side of Hudson's Bay.

Canada consists for the most part of laurentian, devonian, and silurian rocks.

The size and shape of this country operate in controlling the distribution of heat. It is admitted that the greater the land surface the greater the measure of heat; and as the continent of America widens as we ascend in

* The present article is, in considerable measure, a condensation of my work on "The Climate of Canada, in its Relations to Life and Health," to which I refer the reader for ampler information.—W. H. H.

latitude we find the centre of the system of atmospheric circulation north of the geographic equator.

The series of vast lakes and rivers exerts unmeasured influence on the climate of Canada. It would be entering upon too elementary a question to discuss it at length. I may say, however, that the influence which large areas of fresh water exert is in a measure proportioned to their depth rather than to their surface. If the collections of water are deep, their surfaces are steadily maintained at a higher or lower temperature than the surrounding air. In summer the surface waters are heated, and when heated become specifically lighter, and in consequence continue to float upon the surface; during the night a portion of surface water, cooled by the withdrawal of the sun's rays or by the low temperature of the air, becomes denser and sinks, while the warmer water ascends to take the place of the colder; but at no great depth from the surface of these great bodies of water the temperature is uniformly cold, being scarcely modified by our summers and winters.

Canada without its lakes would be like the north of Europe in being both continental and oceanic. But its oceanic features are limited. The cold air from the lakes affects vegetation near their shores, but not at a great distance from them. It is to the lakes and rivers, on the other hand, that we are indebted for so great a range of animal and vegetable life. Thus vegetation in longitude 110° and latitude 54°, upward of seven hundred miles from Toronto, has nearly the same character as it has in the capital of Ontario.

The climate of Canada is more uniform than is that of Europe—the meteorological differences being such as are produced by position alone. It is regarded as a dry climate, yet more rain falls in Canada than in Britain; but it falls in a shorter period, and in larger quantities at a time. The average fall in Canada is fifty inches a year; while in Great Britain the rainfall is but thirty inches. If we seek comparisons in Europe, we find a parallel to the Canadian winter in St. Petersburg, and to the Canadian summer in Paris. But the sky of Canada rivals those in clearness—a clearness which is obscured only for a short period every few days.

It is customary elsewhere to divide the year into seasons of three months each; but this division, arbitrary at best, is totally inapplicable to Canada. Spring and autumn are here of short duration. A line of forty degrees mean temperature, according to Blodgett, passes through Nova Scotia, near Halifax, Montreal, then parallel with the St. Lawrence, north of Kingston, through Toronto, south of Penetanguishene to the Red River of the North. That is the temperature of April, but advance in temperature is uniform for the next two months. The advance is illustrated by corresponding changes in the animal world. The earliest birds, as the song sparrow, begin to sing in the month of March; the robin, also returning from the South while snow yet dapples the ground, makes short and frequent attempts at song; the moose deer leaves his winter haunts about the same period, and approaches the marshes, ponds, and rivers, in search of food; wild-geese move northward about the 22d of April; and the frog, with a regularity that is surprising, begins in the last week of April in Eastern Canada its harsh guttural croaks.

The mean summer temperature ranges from 55° F. in the northern to 65° F. in the southern parts of the country; but the extremes of heat are very great, the thermometer sometimes indicating a temperature more exalted than that of the blood. The mean distribution of rain for the three months of summer is ten inches.

The early part of autumn is a season of peculiar beauty; the transition from the heat of summer to the temperature of autumn is very sudden; the autumn coloring of the leaf in various tints is but the prelude to the rustling of its dry, lifeless form. While the first of these autumn months—September—might be claimed by summer, the last, November, is in reality a winter month; the mean temperature of the latter may be stated at 43° F.

The regularity of the advent of birds from the North, in springtime, is equalled by the regularity of their departure in autumn. A mysterious influence—which has been variously explained by some as the advancing heat, or by others as the demand of impending ovulation—seems to lead various classes of birds to take their departure for the more congenial influences of the South at about the same time; and birds of strongest wing and most rapid flight are very often those which leave the northern portions of Canada with the greatest regularity. Thus the wild-goose, which, according to Dr. Rae, visits the extreme North on April 23d, comes back again to us about the 25th of October.

A foretaste of winter is afforded us by sharp frosts, piercing winds and snowfall, interrupted for a day or two by soft balmy breezes, which we call "Indian Summer," but which the French *habitant* styles:

> "L'été St. Martin,
> Du Soir au Matin."

This is a short period, of uncertain occurrence and of uncertain duration.

In winter the snowfall does not bear a direct ratio to the cold. The largest amount of snow usually falls in the months of December and February, and although occasionally the temperature of those two months falls below that of January, it is only in the aggregate, as considerable allowance must be made for what is termed the "January thaw."

The snow crystals which fall in different months, and in various parts of the country, are very different in form. The aggregated flakes vary in their combination, but in whatever part of the country they are met with, they present as distinct a mathematical form of crystallization as that which characterizes the more lasting crystalline gem from inorganic nature. The snow-crystals are well-defined hexagonal or six-sided prisms, very commonly of a stellar or star form; but the electrical conditions of the air influence the form. Vitreous or positive electricity gives a result different from that given by negative or resinous electricity, but chiefly in the matter of the grouping.

As forests or herbage which cover the surface influence climate, that of Canada is certainly undergoing important modifications. Forest trees cannot be cut down, and the earth cannot be upturned or pierced with drainage-tubes without the climate being sensibly affected.

From the oak and elm and beech and maple on the one side, to the pine and cedar and still hardier lichens, the mixed forest is met with in Canada in rich luxuriance. In some districts the pine and spruce are interspersed with beach and maple; but plants with slender shrunken leaves and feeble stems are nowhere to be met with in Canada. The wild grape flourishes as far north as fifty-two degrees of north latitude, and is abundant in the Kaministiquoia.

As a wheat-growing country Canada equals Russia. From the valley of the Saskatchewan, and from far down the Mackenzie River in the northwest, along the chain of lakes and rivers, wheat of the finest description is grown—inferior in gluten only to that cultivated near the shores of the Mediterranean. Were it not for untimely frosts the wheat-producing power of the northwest of Canada would be greatly increased.

The climate of Canada is highly stimulating. It is a matter of observation by residents and travellers that the thermometer cannot register this quality, though Europeans, accustomed during their lifetime to the use of stimulants, quickly perceive that if they wish to preserve health in Canada the quantity must be diminished: temperance is almost a matter of necessity.

A residence in Canada is attended with certain physiological changes. The transition from youth to manhood is often sudden, the period of childhood being short; but not to climate alone, but to domestic education as well, and to social influence, must be attributed this most unattractive feature. Many of the tissues of the body, as the skin, hair, etc., become drier by a residence in Canada, and physicians recognize still further changes in some of the

internal organs ; but these changes are not prejudicial to life or to health. On the contrary, the maritime and continental features, harmoniously blended in a Canadian climate, are favorable to the highest development of a hardy, long-lived people.

It is generally admitted that a change takes place in the European's constitution after a longer or shorter residence in this country. Between the emigrant of to-day and the children of emigrants of fifty years ago we observe marked differences. The high color which flushes the cheeks and reddens the lips of Europeans fades somewhat, and the skin becomes less soft and moist ; the hair becomes drier and straighter ; the fat, which cushions the cheeks' muscles and gives roundness to the general outline, disappears to some extent ; and the teeth, thanks to a pernicious mode of living, decay sooner.

The various seasons influence persons differently ; but it is, perhaps, the great heat of summer which influences most. The temperature of winter comes next. The milder seasons of spring and autumn exert less influence, being more like those seasons in Europe. In Canada it is not alone the hot weather which acts so severely upon the human body, but, apart from the relaxing influence of heat *per se*, it indisposes to take food in large quantity. It is during the hot weather that mortality is greatest in Canada—very different from what it is in the north and west of Europe, where the mortality is higher in cold than it is in warm weather.

The cold of Canada in winter is severe, but it is not destructive ; the sharp, clear, bracing temperature is more easily and more agreeably borne than is the humid, raw air of a higher temperature. It is remarked that the cold during winter seems to be more superficial, as it were, and to call into activity the capillaries of the surface of the body. A marked difference is noticed between the influence of the cold of Canada, with its low altitude, and the same temperature in high altitudes elsewhere. If, for instance, we ascend Mount St. Bernard till we reach a temperature equivalent to that of a Canadian winter, the air is found to be too vivifying ; respiration becomes too hurried, and among those who permanently dwell there great longevity is rare. In Canada the cold is indeed exhilarating, but not for early destruction. The exhilarating influence of a Canadian winter depends much upon its peculiar electrical condition. The sensations of cold in winter are but relative : when the body is inured to severe cold a moderate degree of elevation is easily felt. It is surprising how easily we adapt ourselves to a climate where the changes in temperature pass through a cycloid very much greater than exists, perhaps, in any other part of the world. Europeans, if sheltered from the piercing winds, inure themselves readily to the severest cold in winter.

The rapidity with which the country has been recently opened up, especially the west and northwest, makes any attempt at correct vital statistics impossible ; but the reports furnished by the surgeons of the American and British armies supply that want to a considerable extent. It has been found that stations improve in salubrity in direct ratio to their proximity to the frontier and to the great chain of Canadian lakes. Canada is the healthiest station in the British Army, Malta alone excepted,—much more favorable to life and health than Great Britain itself ; much more favorable than those favorite stations, Gibraltar or the Ionian Islands or the Bermudas ; and immensely more favorable than Ceylon or Bengal, or any other Indian station.

There are no diseases known in Canada which are not met with elsewhere, though many diseases are greatly modified by residence in Canada.

The selection of climate is oftentimes a matter of some difficulty ; thus, portions of Canada are singularly favorable to consumptives ; but this must be taken with some qualification. The climate is favorable to persons in whom tubercles are being deposited, or are already deposited, or to those who have a condition of lung which seems prepared for the reception of tubercle. But for those in whom tubercular softening exists, or in whom large or even small cavities are found, Canada is not a favorable climate, except, perhaps, that of its western extremity at the Pacific Ocean. The air in the north, otherwise so healthy, is too stimulating under these circumstances ; while that of the east is too humid. Writers on the diseases of hot climates were formerly in the habit of recommending consumptive patients to visit warm regions—to pass a winter in the South of Europe, or in Africa, or in the warmer portions of the American continent ; but there has for many years past been a change in the opinion of physicians on this question, and patients are sent to cold rather than to hot regions. Sometimes patients are sent on whaling expeditions off the coast of Greenland. But whaling expeditions are not easily arranged for, and are attended with risks and discomforts of a nature to counterbalance, in great measure, the advantages of change of air.

The varieties of climate in Canada differ widely, embracing almost every moderate degree of heat and every still more moderate degree of moisture, and affording greater differences than are to be found perhaps in any other country. Its vast extent of territory would account for so great a range ; but, as I have said, north and south are not the only questions where climate is concerned ; and even the poles and the equator are but elements in its formation.

As in Canada we have almost every variety of climate, and as we are not restricted in selection, places must needs be chosen where comfort, which is so essential to enjoyment, may be most easily obtained. Since there has been direct railway communication between the Atlantic and the Pacific coasts through Canadian territory, where the mosses at one end, the umbrageous foliage at the other, and the variegated forests along the route give evidence of the great variety of climate traversed in the eight days' rapid journey, a choice of locality is not difficult. With a country joining two oceans ; with every variety of physical configuration ; with every degree of temperature, and with a moderately varying dew-point, a choice may easily be made by those conversant with the subject, for it must be borne in mind that not temperature alone, nor dryness, nor equability is exclusively to be considered, nor yet the all-important question of comfort, but all these taken in connection one with another. It is pleasing to add that the condition which the medical authorities of the United States Army wisely object to—high temperature and with it a high dew-point—is not met with in Canada. One must be prepared, however, to lay down general rules for the guidance of patients in special cases. The many hundreds of miles of the Atlantic coast afford a selection for one class ; the more sheltered parts of the St. Lawrence valley will suit another class ; the hilly districts in Eastern Canada would benefit a third ; the western lakes would suit others ; the large basins of water, the Saguenay or Gaspé, or Baie de Chaleur, a fifth ; the shores of those inland seas of purest water, another class ; the western regions from Winnipeg to the base of the Rocky Mountains, especially the neighborhood of Banff, another class ; spots here and there on the Rocky Mountains themselves, another class ; the western slopes of the Rockies, another class ; and the varied shores of the Pacific coast, still another class ; and when chronic bronchitis or pleurisy is under consideration, the more genial influence of the Pacific will be found more beneficial. In the months of December, January, and February, and the first two weeks of March, in almost any of these districts, but especially in Eastern Canada, generally as far as the Rockies, the advance of phthisis is checked in persons who have strength enough to live much in the open air.

The healthiness of the climate has been a matter of observation by every writer from Charlevoix to the present day. The early French writers in sending accounts to their "Mère Patrie" were enthusiastic over the purity of the atmosphere, the magnificence of the forests, the transparency of the waters, and the health-giving qualities of the air.

Old age, in Canada, is a green, an active, a vigorous old age. The census shows a large number of persons living from eighty to one hundred years of age. Life assurance companies have found it to their advantage to

change the scale so that Canadian lives may be accepted at a lower rate than British lives. This continues till the age of thirty-six, when the rate is the same; after which it gradually increases, as insurance companies have to take cognizance of a life of greater wear and tear in Canada, which *tells*, in the course of time, even upon the sturdiest.

The healthiness of the climate is, moreover, manifest in the natural increase of the inhabitants. A section of the population—the French Canadian—has increased at a ratio infinitely greater than that of any other country, not even excepting that of Russia. Canada, in this respect, presents a marked contrast to many other countries, where the birth-rate is sometimes alarmingly small. The increase in Canada is, no doubt, due to a considerable extent to early marriages, which are in every way encouraged, and also to an absence, among the married, of that nameless, shameless, crime of marital limitation, which unhappily obtains in many places elsewhere.

A circumstance not generally known may here be mentioned, viz., that the weight of children born in Canada is nearly a pound more than that of the children born in the maternity hospitals in London. If, then, Canadian children are so favorably handicapped at the start, may it not be presumed that they will continue it to the finish? Certainly, up to a certain period in youth they grow more rapidly, and attain greater height at an earlier age than they do in Great Britain; but this may be due, to some extent, to that forcing process which certainly develops but may not solidify. This question, however, is of too extensive a nature to be dealt with here, but this may be stated, that the colonist is superior in strength and height and weight to his progenitor, and the French Canadian markedly so. The Teuton, the Irish, and the Scotch are not yet long enough in possession of the soil to enable one to make trustworthy comparisons between them and their ancestors; but, following the figures furnished by Professor Forbes, of Edinburgh, some years ago, I, on two occasions, established the height, weight, and strength of the students attending the medical schools of Montreal, and I found that the British Canadian, though he could count but one or two generations born in Canada, had gained over his ancestors in height, weight, and strength. The French Canadian could count seven, eight, and sometimes ten generations born in Canada, and the advance in height, weight, and lumbar strength was greater. It is undeniable that the French, in France, have diminished in stature; that wars have carried off the taller; and that revolutions and wars have cut off many of the generators of tall men, till the standard is much less than formerly. In France dynasty has followed dynasty, sometimes with feverishness and unrest; sometimes with violence; sometimes with bloodshed; but always with disturbance of the quiet of the people. And that disturbance of the people's quiet is as prejudicial to development as it is to gestation. In Canada, on the other hand, it has been one almost unbroken chain of undisturbed quiet.

There remains the question of acclimatization, and with this must be considered the habits of the people. In Canada acclimatization has gone on without affecting prejudicially those who are subjected to its operation. There is no sign of decay in those who are in the progressive state. Those coming from Europe to Canada have, it is true, to clothe themselves differently, to take food of somewhat different character, and, very often, to diminish the quantity of stimulants to which they may have been accustomed. It has been pointed out by those who are not favorable to the country that there are local exhibitions of that more general decay which Dr. Knox of evil omen prophesied is the lot of the denizen of the North American Continent, when he says: "Were the supplies from Europe not incessant, a European could not stand his ground in those new countries. A real native, permanent, American or Australian race, of pure Saxon blood, is a dream which can never be realized. Man cannot ever exist permanently in any country to which he is not indigenous; cannot ever become native true-born American; cannot hold permanency in any portion of any continent but the one on which he first originated." The prophet has passed away, and in the country, too, to which he was indigenous, and, notwithstanding his prophecy, the descendants of the Saxon and the Celt present, seemingly, all the characteristics to fit them for the permanent occupation of the soil.

It has been claimed, on the other hand, by writers, that had the aborigines of the country been left to themselves they would eventually have disappeared without hostile action on the part of the white man, on the hypothesis that new-comers are victors in every great struggle for existence. It is claimed to be with men as it is with European plants transferred to Canada. They take vigorous hold of the soil and attain a vigor unknown in Great Britain; and when taken back to the soil whence they came, they there again comport themselves with modesty. The aborigines are rapidly disappearing, but has not the white man changed for them their surroundings? Or had they their own period of active infancy and vigorous age, as they now have that of decay? For are they not representatives of a race much older than the races which have supplanted them; and have they not been associated with the flora that is passing away?

The low birth-rate among the aborigines is pointed out as an evidence of the baneful influence of this climate upon natural increase. But it must be borne in mind that climate is not the only factor in determining prolificness, and that the procreative power in a country has a certain degree of relationship to the ability of the soil to support its inhabitants and to the precarious living of these scattered tribes, some trusting entirely to hunting, some to fishing. Fishing necessarily implies temporary abode, in moderate numbers, at the borders of lakes and rivers; while hunting necessarily implies still more moderate numbers, and a still greater extent of country to roam over. As food is limited in quantity, and cannot be brought along with the natives, and as the necessities of the wild animals impel them to move hastily from one part to another, it follows that food is often insufficient. Scarcity and insufficiency are not less hindrances to population than are the enforced scattering of the tribes, and the enforced neglect of the women by the men of the tribes. Where food is scarce, the men are obliged to keep greatly in advance of the women, and the latter are little valued. There is another cause of limitation among the aborigines: The deformed, among the children, are invariably sacrificed, except where Christianity has stepped in to save. The healthy, strong, vigorous, and well-formed are alone permitted to live. The mother suckles the child, five, six, and seven years, sometimes for a longer time; and during the whole period of lactation the husband does not disturb her. Ante-natal life has its dangers also: the severe toil of the mother; exposure to the inclemency of the seasons; forced marches, etc., are so many risks to the unborn. Among the young children the absence of ventilation, the habits of gormandizing after enforced fasting, and all those hindrances to increasing population inseparable from a nomadic existence, are met with. Add to these, polygamy. Abbé Lacombe states that wherever it exists among the aborigines, the number of births is *smaller* than among the monogamous. This is quite in accordance with what is met with in Eastern Europe, where Christian families, where monogamy exists, consist of a greater number of children than do Mahommedan families in which polygamy is met with.

It is true that the teeth, among the whites, decay at a much earlier period in Canada and in the northern United States, and that has been seized upon as a partial fulfilment of Knox's prophecy. I have fully admitted, in my work on the climate of Canada, the general prevalence of an earlier decay of the teeth; but I have also asserted that the climate has nothing whatever to do with that decay. The aborigines, throughout Canada, have remarkably good teeth. In the extreme north, toothache is unknown. The teeth of the Esquiman, by constant trituration, are sometimes worn away; or a disease in some measure equivalent to rheumatism may cause an occasional crumbling; but toothache is unknown. The Iro-

quois and the Huron Indians have teeth beautifully regular and equally strong. Teeth decay early with us because there is an impairment of the function of digestion. Functional disturbance is the common cause of decay. The Canadian child subjects his digestive apparatus to an ordeal to which it is not equal, and for which it is not prepared. I have elsewhere reduced the causes of this decay of the teeth to several: Taking too much food—therefore decomposition of a large portion of it; taking too hot articles of food into the mouth—therefore cracking the teeth; taking too cold articles—therefore a like result; taking acids and a variety of condiments, vinegar especially—therefore dissolving them; chewing insufficiently—therefore allowing them to rust; drinking while eating, therefore washing food out of the mouth by fluids of various kinds before the first and most important stage of digestion is accomplished; spitting, therefore robbing the food of its first and chief chemical solvent and leaving it unfitted to be acted upon by the gastric juice later on;—in a word, forgetting that the purposes of food are to nourish the body, and to sustain its heat, and not, by the tricks and refinements of the gastronomic art, to spur the appetite beyond its own better sense. *William H. Hingston.*

CANARY ISLANDS. The "Canaries" (*Insulæ Fortunatæ*) are situated in the North Atlantic Ocean, about sixty miles from the west coast of Africa. They lie between lat. 27° 4′ and 29° 25′ north, and long. 13° 25′ and 18° 16′ west. There are seven principal islands in the group, which are named as follows: Teneriffe, Grand Canary, Palma, Lanzarote, Fuerteventura, Gomera, and Hierro. The islands cover an area of 4,000 square miles. They are supposed to be, like Madeira and the Azores, of volcanic origin, but their climate is warmer and drier than that of the islands named. "Their coasts are bold, abrupt, and rocky, and their surface is broken up by mountains, of which the loftiest, *Pico de Teyde*, in Teneriffe, is 12,182 feet high. There are no rivers in the islands, but after heavy rains torrents pour down the mountain slopes and ravines" (Scoresby-Jackson, "Medical Climatology").

Teneriffe is the largest of the Canary Islands, and its capital, Santa Cruz, is annually visited by many invalids. It is, however, less attractive and offers fewer comforts to those in search of health than Orotava, on the northwestern side of the same island. The climate of Orotava is "softer" than that of Santa Cruz. Laguna, on a lofty plain in the northern part of Teneriffe has a much lower range of temperature than Orotava and Santa Cruz. Scoresby-Jackson gives the following table of temperature in degrees of Fahrenheit:

	Santa Cruz.	Laguna.
Annual	71.15	62.63
Winter	64.85	56.42
Spring	68.87	59.75
Summer	76.68	68.29
Autumn	74.17	66.06

While the Canaries are popular as health-resorts, they are, nevertheless, exposed to east and southeast winds, which are hurtful to certain invalids. The climate of the islands is, on the whole, less relaxing than that of Madeira, but it is not by any means bracing.

The class of cases likely to do well at Teneriffe are the early stages of phthisis, asthma, winter bronchitis, gout, rheumatism, and neurasthenia. Apart from Teneriffe and Grand Canary the accommodations for invalids are inadequate. It is the clear skies and dry atmosphere of the Canaries, together with the (in general) mildness and equability of the climate which have given these islands their title to rank as climatic stations of some importance.

In the Grand Canary, *Las Palmas* has recently been made much more attractive than formerly. There is now a good steamboat-landing at this resort, a fine sandy beach, comfortable quarters, and almost daily communication with England. The Canaries may be reached from England by the steamers of the Cape and New Zealand lines. There is also a line of steamers plying between the different islands of the archipelago, thus affording good opportunities for pleasant excursions. Although the Canaries belong to Spain, there are plenty of English residents, and in the chief resorts the English language is sufficient for all practical purposes. Finally, it may be worth mentioning that the more hardy and adventurous can find a variety of "local climates," owing to the difference in altitude of many of the smaller settlements. Invalids should not arrive before November, unless they intend to visit the higher altitudes.

Edmund C. Wendt.

CANNABIS INDICA. This drug owed its introduction as a therapeutic agent to its reputation in the East as an exhilarating and intoxicating drug. It was shown to possess active medicinal properties as an hypnotic and anodyne, and retains its position in the Pharmacopœia, but has never been received with much confidence. The objection to its use has been the great variation in the quality of the drug and the uncertainty of the effect to be produced. This arises from several causes, among which may be mentioned the different seasons in which it is collected, the want of care displayed in the cultivation of the plant, and the age and preservation of the drug, and its preparations. Of late the attention of the profession has been directed to its value, and it has been utilized to a much greater extent than formerly. Greater care has been given to the drug itself and more precision in its preparation; in consequence the old objection to its use is to a great extent removed, as a reliable and trustworthy preparation may now be obtained.

It was formerly thought to be a very powerful toxic agent, but recent investigations have shown that although it may very readily give rise to mild toxic symptoms, it is only where excessive doses have been given that fatal consequences may occur. It has even been said that no well-authenticated instance of a fatal case has been recorded. In experimenting on animals, Dr. Hare found that ten minims of a fluid extract produced the well-marked physiological action in a man, but three to five drachms were given to a dog without a fatal effect, and death was only produced when about one ounce was administered.

Among the many communications that have recently appeared, two particularly deserve attention, as recording the views of careful clinical observers: one by Dr. Russell Reynolds, in *The Lancet* of March, 1890, and the other a report by Professor Germain Sée to the French Academy of Medicine, in the same year. Dr. Reynolds gives the result of some thirty years' study of the drug in mental and nervous diseases. He found it of particular value in the aged when the mental faculties are weakened generally and much restlessness and sleeplessness is an accompaniment. In doses of one-third to one-fourth grain at bedtime a calm and quiet sleep is secured, and the same action may be secured for weeks without increasing the dose. In melancholia and chronic alcoholic delirium of the aged, accompanied by depression, it has acted as an exhilarant, has produced the desired sense of strength, and has secured quiet and rest. In the restlessness of general paralysis and "temper diseases," in both adults and children, it has also been of the greatest service.

In painful maladies it has acted best in those of a functional character, such as neuralgia and migraine, either alone or when combined with constitutional remedies, as iron, quinine, and zinc, when such are indicated. In neuritis it only proves of service when given in addition to mercury, iodine, and other such remedies. It has also proved very serviceable in the formication, tingling, numbness, and other sensory disturbances of the elderly and gouty.

In clonic muscular spasms it has been very successful, such as the convulsions of children and adults due to reflex causes, in epileptiform convulsions due to organic disease of the central nervous system, and in cases of brain tumor accompanied by convulsions and other indications of central irritation. In true epilepsy it has proved useless. In numerous cases it has been given for

a prolonged period until its full physiological action was produced, and yet has failed to influence the disease in the slightest degree. It relieves the distress of spasmodic asthma and has proved very serviceable in spasmodic dysmenorrhœa devoid of metritis or inflammatory causes. In the hands of Dr. Reynolds it failed entirely in chronic and acute mania, sciatica, lumbago, pleurodynia, and in all forms of hysterical pain. It also proved useless in torticollis, writer's cramp, paralysis agitans, and tetanus.

Professor Sée directed his investigations to its use in painful gastric disorders that were not accompanied by any apparent organic change. He considers Indian hemp a true sedative to the stomach without any of the disturbing effects of opiates, chloral, bromides, and similar drugs. Its effect he thinks is due to the sedative action on the pneumogastric nerve. He has used it in all painful dyspepsias and neuroses of the stomach and always found it of value. Its beneficial effect is increased by attention to the state of the secretions and the use of alkalies, purgatives, salines, and antiseptics when such remedies are indicated.

In using this remedy it is advised that the article should always be obtained from the same source. Dr. Reynolds, throughout his many years of practice, obtained the drug from the same establishment and found that although its strength would vary with the seasons, the desired effect could always be obtained. He recommends that the dose, to commence with, should be one-fifth of a grain every four or six hours for adults, and one-tenth of a grain for children, gradually increasing until its effect is produced.

One grain of the extract he has found will produce toxic symptoms in the majority of individuals, if given as an initial dose, but when gradually administered it may be increased to four or five grains with immunity. In some instances a dose of one-fourth or one-third grain has caused mild intoxication. The preparation that he prefers to use is the tincture. The Pharmacopœial strength is one part in twenty and forms a ready means of giving the required dose, especially to children. Dr. Reynolds has also prepared a tincture of double the official strength as more convenient for the fuller doses. This is ordered to be taken on sugar, which is an easy method of administration, and renders unnecessary the disagreeable and uncertain emulsion which otherwise would have to be formed. The pills and solid extract produce an uncertain and delayed action; they are apt to become dry, and are often insoluble. The preparation advocated by Professor Sée is a fatty extract made by dissolving the alcoholic extract in butter by the aid of heat and washing with water. It is given in doses of one-fourth grain three times a day. Other observers are now advocating its use in greatly increased doses, pushing it rapidly to two or three grains if its sedative and anodyne effects are desired. When its action is required in dysmenorrhœa and in pelvic disorders, its use as a suppository produces the desired effects more rapidly.

Analysis of this drug has not produced any preparation that has proved superior to the crude drug. It yields numerous principles, but none of any practical value as a substitute for the drug itself. The poisonous constituent, *tetano-cannabine*, is not utilized and whatever advantage the alkaloid and resin may have is due to the absence of this powerful toxic principle. *Cannabinon* is a resinous, balsamic substance, dark brown in color, of the consistency of treacle; it is insoluble in water, soluble in alcohol and oils. Its taste is disagreeable. It is used as a sedative in mania, hysteria, and sleeplessness, but its uncertainty of action and the production, in many instances, of severe toxic symptoms have led to its disuse. The dose is one-fourth to one or two grains. The alkaloid *cannabine* is a translucent, brown, sirupy liquid with the odor of Indian hemp. Its dose is from one to five grains daily in divided doses, but its use is replaced by what is termed *tannate of cannabine*, which has been recently introduced, and is probably the most useful of all the principles of hemp. In its preparation the poisonous volatile principle is removed and a tannate of the remaining constituents formed. It is a yellow, or brownish yellow, amorphous powder, with a very bitter and astringent taste and a faint odor of Indian hemp. It is slightly soluble in cold water, more so in hot, and freely soluble in hot water that is acidulated with hydrochloric acid; it is also soluble in alkaline solution, and very soluble in acidulated alcohol. The dose is from two to ten grains—which may be increased to twenty grains,—taken an hour before bedtime. It does not produce intoxication and is recommended as an hypnotic of particular service in acute mania and nervous sleeplessness.

Beaumont Small.

CANNSTATT. A watering-place in Würtemberg, Germany.

Location.—Cannstatt is prettily situated in a valley near Stuttgart, from which place it is easily reached by horse-car or carriage. It is less than 700 feet above the level of the sea, has an agreeable, rather warm, and equable climate. It is well sheltered by hills, except toward the south. There are over thirty springs belonging to the saline and chalybeate group. The temperature of the water varies from 50° F. to 70° F. The principal springs are the *Wilhelmsbrunnen* and *Männlein* and *Weiblein*.

Access.—By rail to Stuttgart, and thence by carriage. Cannstatt is also a railroad station, and all the local trains stop there.

Analysis.—In 1,000 parts of the *Weiblein* water there are contained:

	Parts.
Chloride of sodium	2.454
Chloride of potassium	0.031
Chloride of magnesium	0.019
Carbonate of lime	0.893
Carbonate of iron	0.031
Sulphate of sodium	0.581
Sulphate of lime	0.931

A number of springs have been united to feed a large reservoir used for bathing. The prickling sensation of gaseous bubbles on the skin is not unpleasant.

Indications.—The thermal establishments of Cannstatt are modern, complete, and well managed. The waters are employed for every conceivable variety of bath and external application. The resort is chiefly frequented by those suffering from nervous affections, chronic catarrhal troubles, diseases of women, and anæmia. But a great number of other diseases are likewise treated in several special establishments. Thus, skin diseases, scrofula, gout, rheumatism, neuralgias, and paralytic states are said to be treated with satisfactory results. The writer of this article has visited Cannstatt on several occasions and always received a favorable impression of the thoroughness of the methods employed there. The resort is not an international one, however, being little known, and not yet "in vogue" outside of Germany.

Accommodation.—The principal hotel of Stuttgart is the Marquardt, but there are also several moderately comfortable hotels in Cannstatt proper.

Edmund C. Wendt.

CANTHARIDINATE OF POTASSIUM. The application of the cantharidinates to the treatment of tuberculosis was introduced at a meeting of the Berlin Medical Society on February 25, 1891, by Dr. Oscar Liebreich. The value of this drug as a remedy rested on its well-known property of promoting exudation of serum from the capillaries; an effect not only directed to the vessels of the surface of the body, but also produced in various organs, as the kidneys, sexual organs, and lungs, particularly when the drug is administered internally. This is the special action of the drug on the healthy tissues, and he assumed that an irritated condition of any set of capillaries would favor this process of exudation, at which time a dose too small to produce any effect on healthy capillaries would cause an exudation from those inflamed. This would relieve the congested cells and restore the tissues to a more healthy state; and, further, he claimed, as it had been shown that serum possessed decided germicidal properties, it should prove

antagonistic to the growth of tubercle and assist in the effort at repair.

A number of cases treated by his method were shown by himself and some of his colleagues; cases of laryngeal phthisis, lupus, and pulmonary phthisis were all said to be benefited. When the diseased parts could be observed, the action of the drug was such as had been described by Dr. Liebreich, the ulcerated surface being more healthy and showing signs of repair. When the lungs were affected the expectoration became free and profuse, the œdema decreased, and the local condition improved; the fever also diminished, and other constitutional disturbances lessened. Liebreich stated that no reaction followed its use, but other observers reported a slight rise of temperature, headache, disturbed digestion, diarrhœa, etc. If the dose be too great it produces the characteristic symptoms of cantharides-poisoning—pains in the loins, albuminuria, strangury, and hæmaturia.

The cantharidinate of potassium and the cantharidinate of sodium in solution were selected as the salts most suitable for using the drug hypodermically. As the amount of cantharidin in these salts varies greatly, Liebreich advised the use of a certain solution which he had found by experiment to be most suitable. It is prepared as follows: Cantharidinin, 0.2 gramme; potassic hydrate, 0.4 gramme, most carefully weighed and heated over a water-bath in a 1,000 c.c. flask, with about 20 c.c. of water, until a clear solution results; then add water gradually, while still heating, to the full quantity.

Of this solution 8 to 16 minims are administered hypodermically. Its use should not be continued for any length of time; at least every third day should be allowed to intervene without the drug being administered.

The effect on the kidneys must be carefully watched, and the dose lessened, or its administration stopped, should any symptoms of strangury occur. In kidney disease its use is, of course, contra-indicated. To overcome the painful local irritation that frequently follows at the site of injection, it has been recommended to prepare a solution containing cocaine, which prevents the pain. Two parts of the hydrochlorate of cocaine are added to one of cantharidin and two of caustic soda; this is formed into a solution, and $\frac{1}{60}$ to $\frac{1}{120}$ grain is used as a dose. The addition of cocaine is also thought to lessen its tendency to irritate the bladder or kidneys.

This treatment has been extensively applied to all forms of tubercular disease, but it has not proved of sufficient value to warrant its continued use, and it is now rarely resorted to. It undoubtedly produces the action described by Liebreich, causing a freer exudation of serum, etc., but this does not lead to any improvement in the symptoms or tend to any permanent benefit. Post-mortem examinations of patients who have been subjected to this treatment fail to furnish any evidence of repair or beneficial effect on the disease. *Beaumont Small.*

CATARACT. Antiseptic Measures.—The difference of opinion as to the value of antiseptic precautions in cataract operations having disappeared, and their employment having become practically universal, the favorite methods will now be detailed. The precautions to be taken are in regard to the instruments, the operator, and the patient.

It is in regard to the sterilization of the instruments and the manner of bringing this about that the greatest diversity of practice has perhaps obtained and the most different methods have been adopted. The delicate instruments used in ophthalmic surgery must naturally be handled with greater care than many of those employed on other parts of the body. Immersion in solutions of corrosive sublimate corrodes metal and ruins the edge of the knife. A four per cent. solution of carbolic acid has been proved insufficient to destroy the suppurative germs. To bring about this result with certainty, probably no agent is more efficacious than heat, either in the dry or the moist form. Yet each of these has its disadvantages. Steaming or boiling, the latter in simple water or in alkaline solution, is apt to be followed by rusting. Baking at a temperature of 150° Centigrade, continued for an hour or more, is absolutely certain. But all instruments subjected to this must be made with metal handles in place of ivory or bone, and it is doubtful whether the fine knives used for the corneal section would, after such baking, retain a perfect edge. Many operators, influenced by the above considerations, content themselves with immersing their instruments, previously thoroughly cleansed, in a bath of absolute alcohol before the operation, and withdrawing them one by one as they are wanted for use.

The surgeon and his assistant should wear special outer garments. Those made of linen, freshly washed and ironed, answer a useful purpose. The hands should be thoroughly washed in warm water and with soap, scrubbed with a nail-brush, afterwards dipped in alcohol, and, just before proceeding to operate, in a solution of corrosive sublimate, one to three thousand. That the hands are thus made absolutely aseptic is not claimed, the utmost that can be said is that certain sources of danger are averted.

It is well to give the patient a warm bath the night before the operation. The next day the vicinity of the eye is to be carefully cleansed with soap and water, and a compress soaked in a sublimate solution, one to five thousand, should be kept on the eye for at least an hour previous to the operation. Just before commencing, the conjunctival sac may be washed out with the same solution, applied by means of a sterilized glass tube with rubber bulb. Particular attention is to be paid to the state of the lachrymal sac, and its freedom from infectious secretion is to be positively ascertained.

Anæsthesia.—General anæsthesia, brought about by ether or chloroform, has now, in the vast majority of cases, given place to the local anæsthesia induced by cocaine. This agent was introduced and its properties explained by Koller in 1884. Its use has become general. Employed ordinarily in the form of the hydrochlorate, and in a solution varying from two to five per cent. in strength, its contact with the eye brings about anæsthesia of the conjunctiva and cornea, coming on in from one to two minutes and lasting some ten minutes. In an operation for the extraction of cataract it should be applied two or three times. It is well to remember that the sensitiveness of the iris is not materially affected by the cocaine, and to prepare the patient for a certain amount of pain in case an iridectomy forms part of the operation. Besides producing anæsthesia of the surface of the eyeball, cocaine brings about other changes. It contracts the blood-vessels of the iris, and thus gives rise to a temporary mydriasis; it empties also the conjunctival blood-vessels. On account of this double effect the annoying hemorrhage that sometimes so much embarrasses the performance of an extraction is much less likely to occur. There is also noticed a wider opening of the lids and a lessened tendency to wink. Finally, the intraocular pressure becomes slightly reduced.

If the surgeon finds it impracticable to prepare a sterilized solution of cocaine on the spot, he may use a one to five thousand solution of sublimate as a menstruum. It is best to prepare the patient for a slight smarting sensation when the first application is made to the eye. This very rapidly disappears.

Extraction of Senile Cataract without Iridectomy.—Toward the close of the article of which this is a continuation, written some half dozen years ago, the hope was expressed that experience would before the present time have demonstrated the true value of iridectomy in connection with extraction, and have either established the grounds of its necessity or indicated the propriety of its omission. That hope has proved fallacious. Opinion on the subject is still divided, although it is but just to admit that the advocates of simple extraction constantly appear in larger numbers, and assume a bolder front. Unanimity, however, has not been attained. Operators of skill and of established reputation are to be found ranged on either side. At the Heidelberg Congress in 1888 Critchett brought the matter home to all present by propounding a simple question. "If one of you," he said, "were the victim of a cataract, which operation would you wish to have performed, that with iridectomy,

or the simple extraction ?" Unquestionably the majority of the members would have then pronounced in favor of the former, although the minority was large and influential. It is difficult to say which party would, at the present day, be the more numerous.

The advantages of the non-performance of an iridectomy are simply and concisely stated by Professor Pflüger (*Kl. Monatsblätter für Augenheilkunde,* May, 1892, p. 161). He considers the return to simple extraction to be the greatest improvement in the cataract operation that has occurred for twenty-five years, and for the following reasons:

The conservation of the normal pupil combines optical with antiseptic advantages, in regard to the first part it having been proved that the corneal refractive power is at its best in the centre of that membrane; moreover,

(1) There is no wound of the iris, and hence far less likelihood of a depôt for the collection of offensive, that is, infectious material;

(2) There is no bleeding into the anterior chamber, to obscure the subsequent steps of the operation;

(3) The wound is protected by the intact iris from contact with fragments of capsule, the presence of which so often causes slow healing and secondary infection, leading it may be to chronic irido-cyclitis and even to sympathetic affection of the other eye;

(4) There is a certain amount of protection against loss of vitreous;

(5) Pflüger's experience leads him to think, strange as the fact may appear, that there is less danger of secondary glaucoma in the case of a simple extraction.

It is not asserted by either side that the percentage of corneal suppuration is affected by the performance or non-performance of an iridectomy. Stress is laid on the claim that, after successful simple extraction, the excentric vision is better and light better borne. On the other hand, it may be replied that the iridectomy need not be a large one, and that being made directly upward it is largely covered by the upper lid, thus ensuring a considerable use of the centre of the cornea.

Furthermore: 1. Considering the extent of the corneal wound, as well as the frequently large solution of continuity of the conjunctiva itself, the additional terrain afforded by the iridectomy for the collection of infectious material would be a matter of small account.

2. Bleeding is reduced to a minimum by the action of the cocaine, and frequently is entirely absent.

3. If prolapse of the iris, or even dislocation of the pupil occurs, the capsular fragments may yet come in contact with the wound, and these capsular fragments, as well as cortical remains, can be both more perfectly detected and thoroughly removed where the area is laid bare by an iridectomy.

4. That the statistics of simple extraction show a lessened percentage of vitreous prolapse, as compared with the Graefe operation, is not as yet universally admitted.

5. The same may be said in regard to the occurrence of glaucoma. The experience of individual operators is here at variance. Dr. Knapp, in 1890, reported three cases of glaucoma as occurring among one hundred simple extractions (*Archives of Ophthalmology*, vol. xix., p. 299).

There are two serious drawbacks to simple extraction:—

The first is the difficulty in clearing the pupil of cortical and capsular remains, after the lens has been delivered. It is obvious that, with an iridectomy, there is a larger pupillary area in view and a wider aperture for the extrusion of whatever may occupy it. Moreover, the manœuvres we generally employ for the clearing of the pupil, the tilting and rubbing, tend to maintain, if not to produce, the presence of the iris between the lips of the wound, and to render its ultimate reposition more difficult.

This leads directly up to the main objection to simple extraction, the liability to iris prolapse. This accident is met with in from seven to ten per cent. of all cases of this operation. Its disadvantages are the change thereby wrought in the corneal curve, the dislocation of the pupil, the lengthened convalescence entailed, and the tendency to cystoid cicatrization of the wound. It is most likely to occur in consequence of a sudden motion or injudicious effort on the part of the patient within the first few days after the operation, and may be brought about by the forcible contact of the hand with the eye during sleep. The wound being ruptured, the aqueous humor escapes, and carries with it the iris, which remains incarcerated between the lips of the wound. A sudden sharp pain is sometimes felt and arouses suspicion as to what may have occurred. But there are cases where no imprudent motion is known to have taken place, and no warning has been sounded, and yet where the first inspection of the eye, several days after the operation, reveals an extensive iris displacement.

The tendency of the eye to undergo this accident is well illustrated by the statistics of a third series of one hundred cataract extractions without iridectomy, published by Dr. Knapp (*Archives of Ophthalmology*, vol. xix., p. 280).

In seven of these cases iridectomy had to be performed during the operation.

In two cases the iris folded itself over the knife and was excised.

In eight cases prolapse and incarceration of the iris occurred during the healing process.

Eighty-three of these patients therefore recovered with fair, round pupils, fifteen either had iridectomy performed or would have been better off had this been done.

Performance of Simple Extraction.—There is but little to add to the account of this operation given in the article which the present one is intended to supplement. The long, narrow knife of Graefe may be used for the corneal incision, the puncture and counter-puncture being made just above the horizontal meridian of the cornea, in the transparent periphery of this membrane, the apex of the cut alone encroaching on the limbus. This is the course taken by experienced operators like Knapp, who aim at the avoidance of the peripheric section of former years. The capsule opening is made by some at the same time, and with the same knife used in the incision; by others with a special cystitome, and may be central or peripheric, either method having its advocates. Sometimes a piece of the anterior capsule is removed with forceps specially constructed for this purpose. After the delivery of the lens, the pupil, if still occupied by fragments of cortical or remains of capsule, may be freed by judicious manipulation, or irrigated with a sterilized solution of boric acid or common salt, either one-half or one per cent. in strength. These solutions should be slightly warmed and but little force used in their introduction. For this reason the syringe originally employed by McKeown will be found less manageable, as well as more difficult to sterilize, than the apparatus of Lippincott ("Transactions American Ophthalmological Society, Twenty-seventh Meeting." p. 115), or the "undine" of Wicherkiewicz. The writer has modified the latter instrument by attaching to its large aperture a short rubber tube, ending in a glass mouthpiece. Both hands of the operator are thus left free; he holds the mouthpiece between his teeth, and is enabled at will to modify the pressure to any extent, or even to reverse it and withdraw masses of cortical by suction into the apparatus itself. Solutions of corrosive sublimate are no longer used for irrigation, on account of the corneal opacities they were found to occasionally induce. Care must be taken to keep the opening of the irrigator as far from the pupillary edge as possible, prolapse of the iris being readily encouraged by its too immediate contact with this region.

After the clearing of the pupil and anterior chamber have been completed the iris must be carefully replaced, there being no better instrument for this purpose than a flat, narrow rubber spatula. If reduction be found impossible, or the iris shows a tendency to fall back into the wound, a small iridectomy must be made on the spot. In any case a solution of eserine (one per cent.) or pilocarpine (two per cent.) should be dropped into the eye before closing it.

Every operator has his favorite method of dressing the eye after extraction. A circular piece of linen, dipped in a solution of corrosive sublimate, one to five hundred, may be applied directly over the closed lids, the orbital cavity then packed with corrosive cotton, and the whole retained in place by a few turns of a light roller. These dressings may be withdrawn from the steam sterilizer, if one be provided, at the instant they are needed.

It has of late been seriously proposed by certain surgeons that the non-operated eye be left unguarded, that only a light dressing be applied to the other, and that the patient be kept in an undarkened room and allowed much freedom of motion. Good results are claimed from such an absence of treatment. This, if true, would reverse our traditions and revolutionize our practice. But as yet the only evidence in its favor is that of vague assertion, unsupported by definite statistics. Its advocates are at present few.

Iris prolapse being, as has been stated, often due to the sudden escape of the aqueous humor, consequent on a rupture of the corneal wound, an ingenious means of obviating this has been devised by Dr. H. B. Chandler, of Boston, and proposed by him as a modification of the operation. He makes a small opening in the iris in order to allow the free escape of the aqueous, which collects behind this membrane, and claims that this prevents prolapse.

His description of the operation is as follows: "After making a corneal cut, exactly at the cornea-scleral junction, a very small piece of iris, about one or two millimetres from the periphery, is caught up, either by means of a fine iris forceps, with teeth situated on the lower portion of the blade, as near the point as possible, or by means of a sharp hook, the bent portion being at right angles and about one millimetre long, and gently drawn out, is cut horizontally as close to the gripping instrument as possible; this leaves a small round opening, not more than one to two millimetres in diameter" (*Boston Medical and Surgical Journal*, October 16, 1890, p. 366).

For two or three days after a simple extraction greater quiet is necessary than is the case when iridectomy has been performed, the patient being cautioned to avoid straining and all sudden exertion. The occurrence of severe pain in the eye, or even a feeling of irritation, such as might proceed from the presence of a foreign body, should arouse suspicion of prolapse. If this comes on within two days after the operation the eye must be opened and the protruding iris reduced or excised. Otherwise it is better to leave it alone until the wound is thoroughly consolidated. After a lapse of several weeks the prolapse, if it shows no signs of flattening, may be excised or cauterized.

The exclusive employment of one method of extracting cataract would seem unwise. Each case must be taken on its own merits; its history, the condition of the eye, and the disposition of the patient carefully considered, and the operation selected that seems likely to be followed by the best results. Doubtless a successful simple extraction leaves the eye in a more normal condition, and thus affords a more perfect result. To gain this result the operator requires a maximum of experience and skill, while the patient must be prepared for a somewhat more burdensome convalescence, and must also be willing to incur a slightly increased risk of accident.

Hasket Derby.

CHANNEL ISLANDS. This group of islands, belonging to England, although geographically French, has long been favorably regarded as possessing certain climatic advantages.

Location.—The Channel Islands are small, their total area being only seventy-five square miles. The best known of the group are Jersey, Guernsey, Alderney, and Sark. The first-named is perhaps the most popular as a health-resort. These islands are situated in the great Bay of St. Michael, in the English Channel, and at a short distance from the western coast of Normandy.

Access.—The islands are easily accessible from France. From England a steamer, leaving Southampton daily, reaches Jersey in eight hours. The actual distance from Jersey to *Carteret*, in the Department of *Manche*, is only thirteen miles. St. Helier's, the chief town and port of Jersey, lies at the eastern extremity of St. Aubin's Bay.

Indications.—The Channel Islands are resorted to principally by invalids with "weak chests" and neurasthenia. According to Dr. Hooper, the monthly and seasonal variations in temperature are as follows:

	Degrees Fahr.		Degrees Fahr.
Annual mean	50.06	May	57.08
Winter "	43.82	June	61.51
Spring "	50.97	July	63.50
Summer "	62.84	August	63.72
Autumn "	54.63	September	59.82
January	41.58	October	55.65
February	44.02	November	48.42
March	45.75	December	45.27
April	50.09		

The number of rainy days is less than in England, although the actual precipitation of moisture is greater. It is important to remember that the climate, although mild and equable, is very humid. Dr. Scholefield speaks as follows on this point (Scoresby-Jackson, "Medical Climatology"):

"Besides its insular position, the island (Jersey) is everywhere thick set with wood, every little section of ground being hedged in with four rows of trees. The island, moreover, is continually intersected at intervals of a few hundred yards by pathways, beset with their double file of trees, planted on high embankments. Here neither the sun's rays can penetrate, nor can currents of air freely ventilate the earth.

"Of course, in the absence of high mountains, the islands are exposed to every variety of wind, and frequent gales are observed. Westerly winds predominate. The cold northwest winds of spring are apt to annoy invalids. Apart from this the islands enjoy an equable, soft, humid atmosphere, with astonishingly mild days, and very little frost or snow. The day and night variations of temperature are slight. The climate is thus rather relaxing, and patients requiring a vigorous, bracing air and exhilarating conditions should not be sent there."

Edmund C. Wendt.

CHARLOTTENBRUNN. A watering-place in Silesia, Germany.

Location.—Charlottenbrunn is prettily situated in a valley, at an elevation of 1,300 feet above the sea. The hills afford it ample protection against the cold north and northwest winds, and leave it exposed only to the warmer southern breezes. Pine-woods surround it. The springs are cold, alkaline chalybeate ones. But the place owes its reputation quite as much to its climatic advantages as to the mineral waters. It is a quiet spot, and only semi-fashionable. Season, May to October.

Access.—Bad Charlottenbrunn is a railroad station on the Dittersbach-Glatz Railroad.

Analysis.—The *Charlottenquelle* and *Theresienquelle* are both moderately powerful alkaline iron springs, having the usual composition of chalybeate waters.

Indications.—Neurasthenia, heart disease, chlorosis, and all diseases with a tendency to anæmia, derive benefit from a course of these waters.

Accommodations.—Attractive hotels and boarding-houses, modern thermal establishments, with all comforts, are found here. Milk, whey, kefir, and "herb-juice" cures are special features.

Edmund C. Wendt.

CHÂTEL-GUYON. A watering-place in the Department of Puy-de-Dôme, France.

Location.—Châtel-Guyon is charmingly situated in a beautiful region of Auvergne, and at an elevation of 1,300 feet above sea-level. The climate is pleasant and equable. There are over twenty saline chalybeate, magnesia springs, their temperature varying from 50° F. to 110° F. The French lay great stress on the purgative quality of these waters. But they cannot in any way compare with those of Carlsbad. The water contains free carbonic-acid gas, and the baths are said to be both

tonic and soothing. On account of the bubbles collecting on the skin, they are called "Champagne-baths."

ACCESS.—By the Paris, Lyons & Mediterranean Railroad to Riom, *viâ* Nevers. Thence by carriage in fifteen minutes to Châtel-Guyon.

ANALYSIS.—According to Lefort, the Deval spring contains in 10,000 parts of water:

	Grammes.
Hydrochloric acid (in combination)	21.33
Sulphuric acid (in combination)	2.93
Silicic acid	1.26
Carbonic acid (in combination)	10.92
Carbonic acid free	13.50
Potash	1.12
Soda	12.87
Magnesia	6.70
Lime	9.90
Oxide of iron	0.24
Alumina	0.08

INDICATIONS.—These springs are chiefly employed in gastric and hepatic derangements, associated with constipation, as well as in female diseases with a tendency to anæmia. But French physicians also recommend them in gout, diabetes, Bright's disease, and many other chronic ailments. Taken at the rate of about four to six glasses a day, they are purgative, but smaller quantities fail to act on the bowels. The season lasts from the middle of May to the middle of October.

ACCOMMODATIONS.—There are several bathing establishments, with the necessary appliances, but the *Établissement Brosson*, being the most modern, is to be preferred. Hotels fairly good. The place is not a fashionable one. *Edmund C. Wendt.*

CHLORALAMID. Introduced in 1889, by Professor von Mering, of Strasbourg, for its hypnotic properties, it is now looked upon as one of the most useful drugs we possess for this purpose. It results from the chemical combination of two parts of chloral anhydride, CCl_3 CHO, and one of formamide, CHO NH_2; its formula is CCl_3 CH. OH, $CONH_2$. It is not a mechanical mixture, and would be more correctly named chloral formamide, or formiate of chloral. It occurs in white crystals, which have a faint bitter taste, no odor, and are neutral in reaction. It is soluble in cold water, one part in ten, and in one and a half part of alcohol. The salt should never be dissolved in hot water, or heated above 120° F., as at that temperature it decomposes. It is also decomposed by alkalies and alkaline carbonates. It is compatible with weak acids which increase its solubility and render the solution more stable.

Chloralamid is supposed to be decomposed in the circulation by the free alkalies in the blood, and its hypnotic action produced by the chloral set free. The depressing effect on the respiration and heart does not follow, as this is counteracted by the stimulating action of the formamide.

In addition to this absence of depressing action, it has numerous advantages. It is free from any disagreeable taste, and its solubility renders it easy of administration. It does not derange the digestive organs, and no dangerous or alarming symptoms follow its use. It is not followed by headache, giddiness, or any disturbance of the nervous system. The sleep induced is tranquil and easy, and the awakening gradual and pleasant. It follows in from half an hour to one and a half or two hours after taking the dose, and lasts for five or eight hours. Occasionally a drowsiness continues, or the sleep is much prolonged, but it has never been found to be of serious import. The drug does not possess any cumulative action, nor does it give rise to a craving. It may be administered for a prolonged period without it being necessary to increase the dose.

Since its introduction, chloralamid has been used with safety in all forms of insomnia. It has proved of greatest service in the sleeplessness of a purely nervous origin, especially when unaccompanied by pain, or with pain very slight in character; in nervousness, in hysteria, in neurasthenia, in old age, in spinal diseases, and in chronic alcoholism, its effect will be very decided. When pain is very marked its action is not to be depended upon, but reports of its use in such cases show that it may be of much benefit in locomotor ataxia, and in the pains arising from aneurism and neuralgia. In chronic mental diseases, as melancholia, and mania unaccompanied with much excitement, it has proved of marked benefit. In cardiac disease where chloral hydrate cannot be used, it may be given with perfect safety, and in such cases as cardiac asthma, dyspnœa, its happiest results are obtained.

In febrile states, as in phthisis and typhoid fever, it acts favorably; in the former it lessens the cough and night-sweats, and lessens the depression that accompanies these symptoms. The effect is thought to be due to its stimulating action on the respiration which promotes the respiratory changes, and lessens the carbonic acid in the blood. In whooping-cough, laryngismus stridulus, as well as in pulmonary asthma, the drug not only produces sleep, but also allays the disease, the paroxysms becoming less severe, and the intervals more prolonged.

The dose advised when the drug was first used was from twenty to forty-five grains, and this has been very generally adhered to. The average dose employed is about thirty grains. As a rule, it is advisable to begin with a smaller dose of fifteen to twenty grains, when the insomnia is not accompanied by pain or excitement. On account of its solubility in alcohol, it is easily given in solution diluted with some aromatic elixir. Brandy or whiskey is a favorite means and adds to its beneficial action. If alcoholic solution is not desired, dilute hydrochloric acid will be found to serve the purpose. It may also be given in cachets. For whooping-cough and other spasmodic affections, it is given in doses of two grains every two hours. Enemata may also be employed when such a means of administering the drug is desired. The following formula is recommended: Chloralamid, 14 grains; dilute hydrochloric acid, 3 drops; alcohol, 20 drops; water, 3 ounces. *Beaumont Small.*

CHLORALIMID (Trichlorethylidenimide), CCl_3 CH NH. This substance is obtained by the action of acetate of ammonia on chloral hydrate; it may also be formed by heating chloral-ammonia. It is a crystalline acidular powder without taste, smell, or color, insoluble in water, soluble in alcohol, ether, and oils. It is not affected by heat or moisture. It possesses similar properties to chloralamid, but is more active. As an hypnotic, it is given in doses of from five to thirty grains. It is introduced as a substitute for chloral hydrate and chloralamid. It has not the acrid taste of the former nor the bitter taste of the latter. In smaller doses it is said to have an antipyretic and analgesic action. This drug has not been used to any extent, and its superiority to chloralamid has yet to be determined. *Beaumont Small.*

CHLOROBROM is the registered trade name of a combination of chloralamid and bromide of potassium. This combination, which possesses the active properties of both its constituents, has recently been advised by Professor Charteris, of Glasgow, as a remedy for seasickness. He had used it in many cases with very gratifying results. A dose is given after the stomach has been emptied of its contents, the sense of depression is relieved and nausea checked, a quiet sleep follows, from which the patient awakes relieved of all the distressing symptoms. The remedy may be prepared as follows: Chloralamid, bromide of potassium, of each one and a half drachms; water, 2 ounces; syrup, 1 ounce. One to one and a half tablespoonful for a dose.
Beaumont Small.

CHLOROFORM; HYDERABAD COMMISSION. Chloroform during the past few years has received its share of attention (see article on Anæsthetics) and a large amount of experimental research has been devoted to anæsthetics. Perhaps the most important work done on this subject since the use of anæsthetics was introduced, has been the investigations and report of what is known as the Hyderabad Chloroform Commission. In 1888 the Nizam of Hyderabad appointed the first commis-

sion, composed of Surgeon P. Hehir, M.D., I. A. Kelly, L.R.C.P.S. Ed., and A. Chamarette, I.M.S., to perform a series of experiments upon dogs with chloroform, expressing a wish that they should have a practical bearing on the way in which the administration of the anæsthetic ought to be conducted in the human subject. This commission was formed at the suggestion of Surgeon-Major Lawrie, President of the Hyderabad Medical School. Mr. Lawrie had been a pupil of Syme, of Edinburgh, and retained the views of that eminent surgeon regarding the action of chloroform. Professor Syme had always maintained that chloroform was a safe anæsthetic if properly administered; that its toxic action always showed itself on the respiration before the heart was affected, and that no accident would occur if the respiration was carefully watched.

Opposed to this was the very generally accepted view of what is known as the London school, which considers that the heart is the source of danger, and that death during chloroform anæsthesia was due to its failure.

The purpose of the commission was to inquire into the effect of the anæsthetic on the respiration and heart, and the value of artificial respiration to resuscitate when a fatal termination was threatened. A great number of experiments were made upon dogs, to which chloroform was given in various quantities and under varying conditions, to produce a fatal result. The conclusions reached were in accord with the views of Mr. Lawrie; in every instance the respiration ceased before the heart, and where artificial respiration was commenced when danger was indicated by the breathing, recovery followed, but if precautions were neglected until the pulse gave warning, it was too late to resuscitate. The report concludes with the opinion "that death from chloroform narcosis in dogs is absolutely avoidable, and ought never to occur from surcharging of the blood with chloroform. Once anæsthesia is induced, so long as the respiration is kept up there is no fear of a cumulative action—the drug is rapidly eliminated. Interference with this elimination brings about changes in the respiratory mechanism which ought to arouse suspicion and prepare us for artificial respiration."

When the editors of the London *Lancet* became aware of these experiments and the conclusions so much at variance with their own, they criticised the latter rather severely. It was thought that such important conclusions were arrived at rather hastily, and the experiments were not considered sufficiently precise to justify their acceptance.

In consequence, the Nizam, with great liberality, decided to have another commission appointed to repeat the experiments of the former commission in a more scientific and exact manner. A check for one thousand pounds was forwarded to the editors of *The Lancet*, that they might select any one they wished to conduct the experiments in such a manner as they might think necessary. Dr. Lauder Brunton was chosen and sent to India as their representative. His qualifications were all that could be desired: he was an authority in therapeutics and was known to hold views not in accord with the conclusions of the former commission.

The second Hyderabad Commission was composed of Surgeon-Major E. Lawrie, M.B. Ed., Dr. Lauder Brunton, F.R.S., Surgeon-Major G. Bomford, M.D. Lond., Dr. Rustomji of the Nizam's Medical Service, and associated with them were the members of the former commission. The experiments were begun in October, 1889, and continued for some two months. They were carried on in the hospital in connection with the Hyderabad Medical School, and the native government afforded every facility for making the work as thorough and perfect as possible. The most approved apparatus and appliances were provided for observing the action of the pulse, the respiration, and the blood pressure.

The objects kept in view by the commission were the suitability of chloroform as an anæsthetic, the effect of pushing it until dangerous symptoms or death took place, and the modifications of the anæsthesia that were effected by various degrees of asphyxia, by shock, and by the administration of various drugs.

The experiments numbered over four hundred and thirty. The majority were upon dogs and monkeys, but some were made upon horses, goats, cats, and rabbits.

Two methods of administering the chloroform were chiefly employed. In the first a known quantity was allowed to evaporate in a certain amount of air, and the animal made to breathe the mixture, in the other method a certain amount of chloroform was administered without attention being given to the amount of air inhaled.

To keep a record of the blood pressure two tracings were taken on different drums. One recorded the pressure throughout the whole experiment, but was too slow to indicate any variation in the pressure during the diastole and systole of the heart, the other was taken on a rapidly revolving drum and would indicate the slightest variation. The tracing of the latter would have been too lengthy to preserve, but it was so arranged that the pressure could be taken at any moment and for any length of time during an experiment. In certain instances the motion of the heart was registered by a needle inserted through the chest-wall and into the heart, and the movements conveyed by means of a thread extending from the free end of the needle to a lever writing on the moving surface of the drum.

The records of the respiratory movements were obtained by inserting a needle through the chest-wall into the diaphragm, the movements of the free end being recorded. All these records were photographed and reproduced for publication, and, together with the detailed account of the experiments, provide an amount of evidence which any one may inquire into, and by its means corroborate or disprove the conclusions arrived at by the commission. The work of the commission, including the account of the experiments, the tracings, and a large number of letters and papers, has been published in the lengthy report issued. For the report itself, the pages of the London *Lancet* for 1890 may be consulted.

The result of their work was to corroborate the conclusions of the first committee, and these conclusions were fully concurred in by Dr. Brunton, who became convinced that the respiration was the part first affected and should be watched for signs of danger.

The commission agrees, up to a certain point, with many of the views of their opponents. It is admitted by all that there is a gradual fall in the blood pressure throughout the administration of chloroform, and that this may terminate in death. The commission, however, hold that this is due to impoverished blood acting on the medulla and producing vaso-motor paralysis; the others consider it due to a direct depressing action on the heart itself. Both sides also agree that early in the administration of the anæsthetic a rapid fall in the blood pressure frequently occurs. Upon this fall the greatest interest centres, as it is at this period that so many fatal results occur. The commission say this fall is due to accidental causes, producing asphyxia, and that it might always be avoided by care in administration. The asphyxia by acting on the vagus reduces the action of the heart and lessens the supply of poisoned blood. They consider the slowing of the circulation as nature's method of protecting itself. The opponents to this view hold that it is due to a direct paralyzing action on the heart.

A series of very valuable experiments have since been made by Professor McWilliam, of Aberdeen, who demonstrated that with this early fall in blood pressure, a dilatation of the heart takes place, in some instances, even before the reflexes are lost. When this becomes extreme the heart fails to contract, although it may continue to beat in a feeble and uncertain manner. These observations have since been confirmed by many others, among them, Dr. Hare, of Philadelphia.

In consequence of such a diversity of opinion in such an important subject we are left in a very unsettled and unsatisfactory state of mind. Fortunately at this juncture His Highness the Nizam again comes to the rescue, and in a very creditable and liberal manner determines upon another commission, with the hope of reconciling the opposing views. The appointment of Dr. H. A. Hare to conduct the investigation will give general satis-

faction, and is all the more gratifying as his views are known to be in opposition to those of the last commission, thus indicating an earnest desire, on the part of the Nizam, to have all sides generously treated.

The following conclusions of the second Hyderabad Commission are reproduced in full, as they are of historic importance and will be of interest in connection with the work of the forthcoming commission :

1. Chloroform, when given continuously by any means which insures its free dilution with air, causes a *gradual* fall in the mean blood pressure, provided the animal's respiration is not impeded in any way, and it continues to breathe quietly without struggling or involuntary holding of the breath, as almost always happens when the chloroform is sufficiently diluted. As this fall continues, the animal first becomes insensible, then the respiration gradually ceases, and lastly, the heart stops beating. If the chloroform is less diluted the fall is more rapid, but is always gradual, so long as the other conditions are maintained ; and however concentrated the chloroform may be, it never causes sudden death from stoppage of the heart. The greater degree of dilution the less rapid is the fall, until a degree of dilution is reached which no longer appreciably lowers the blood pressure or produces anæsthesia.

2. If the inhalation is interrupted at any stage, the fall of pressure still continues at a rate which depends altogether on the rapidity of the fall while the chloroform was being inhaled. This after-fall is probably due to absorption of a portion of the residue of chloroform in the air-passages after the stoppage of the inhalation. In this way it often happens, if chloroform is given rather freely, that, though the respiration may be going on when the chloroform is discontinued, it afterward stops.

3. If the administration of the chloroform is stopped at an early stage, the pressure very soon begins to rise again, and gradually becomes normal ; but if the chloroform is pushed further, there comes a time, not easy to define, when the blood pressure and respiration will no longer be restored spontaneously, although the heart continues to beat after the inhalation is stopped.

4. If the fall has been very gradual it may occasionally happen that the respiration stops completely, and still the blood pressure rises again, the respiration recommencing spontaneously in the course of the rise. In the same way, when the inhalation has been discontinued, the respiration may stop during the after-fall of the blood pressure and begin again spontaneously. As a rule, if the respiration has stopped, or even becomes slow and feeble at the time when the inhalation is discontinued, and artificial respiration is not resorted to, the fall in blood pressure will continue until death ensues.

5. There are two conditions which frequently disturb the gradual fall of the blood pressure, viz., struggling and holding the breath—and it is only by great care that they can be avoided in animals.

6. Struggling, independently of any change in the respiratory rhythm, appears generally to raise the blood pressure. In one case of a dog much weakened from phosphorus, the pressure fell every time he struggled.

7. When struggling is accompanied, as it often is, by acceleration of the respiration and pulse, especially if the respiration is deep and gasping, it leads to a more rapid inhalation of chloroform, and consequently to a more rapid fall of blood pressure and a greater after-fall. In order to keep the chloroform cap or inhaler in its place during the animal's struggles, the administrator is obliged to hold it down more tightly over the nose and mouth, and this materially assists in hastening the rapidity of the inhalation, and consequently of the fall in blood pressure.

8. The effect of involuntarily holding the breath—which, as anybody can prove by experiment upon himself, must happen when an inhaler saturated with chloroform is first applied to the face—is much more remarkable, the pressure often falling with great suddenness, while the heart's action is markedly slower. As soon as the animal draws breath again, the pressure rises as suddenly as it fell, but the gasping respirations which succeed then cause very rapid inhalation of the chloroform, with immediate insensibility and a rapid fall of blood pressure, which quickly becomes dangerous.

9. The combination of struggling with alternate holding the breath and gasping, which results if chloroform is applied closely to the face without sufficient dilution with air, causes the violent fluctuations, and then a speedy fall of the blood pressure, which very soon leads to a dangerous depression with deep insensibility and early stoppage of the respiration. The after-fall under these circumstances is rapid and prolonged. It is this combination of events which causes struggling animals to go under chloroform so quickly.

10. The effect of holding the breath may occasionally cause a temporary fall of blood pressure after the chloroform inhalation has been stopped, or even when the animal is quite out of chloroform. This fall is recovered from directly the animal breathes again.

11. Slight continuous asphyxia, such as is produced by pressure on the neck by straps, a badly fitting muzzle, or hindrance of the chest movements by the legs being too lightly bound down, give rise to exaggerated and irregular oscillations of the blood pressure, and slowing and irregularity of the heart's action. If it leads to, or is accompanied by, deep gasping inspiration, it is apt, like anything else which causes this, to increase the intake of chloroform, and bring about a rapid decline of blood pressure.

12. Complete or almost complete asphyxia, as by forcibly closing the nose and mouth or closing the tracheal tube after tracheotomy, has an effect similar to, but more marked than, that produced by holding the breath, and the character of the trace corresponds precisely to that produced by irritation of the peripheral end of the cut vagus. The pressure falls extremely rapidly, sometimes almost to zero, and the heart's action becomes excessively slow, or even stops for a few seconds. If the Fick trace of Experiment 148 be compared with the photographic reproduction of Trace A, of the Glasgow Committee, it will be seen that they are identical, and that the slow action of the heart with great fall of pressure, which the Glasgow Committee attributed to some capricious action of chloroform upon the heart, was undoubtedly due to asphyxia.

13. This effect of asphyxia is the result of stimulation of the vagi. The proof of this is (*a*), that the trace corresponds exactly, as stated above, to that produced by direct irritation of the vagus ; (*b*), division of both vagi entirely abolishes it, and (*c*), the administration of atropine, which paralyzes the vagus, also abolishes it.

14. In Trace 158 (Fick 4), which was taken during asphyxia after a full dose of atropine, it will be seen that there is an alternately slow and rapid pulse according to the phase of the respiratory movement, but no continued slowing of the heart, as in vagus irritation. But there was still a distinct fall of pressure after the atropine when the breath was held, and it was thought that the slowing of the pulse above noted in this condition might be due to the disturbance of the heart from tension in the pulmonary vessels in the absence of respiratory movement, rather than to irritation of the vagi. To test this point Experiment 184 was instituted. In this experiment the dog's chest was forcibly inflated with bellows connected by a tube with the trachea, and the effect of this proceeding was to cause a fall of pressure and slowing of the heart exactly the same as involuntary holding of the breath. The dog was then poisoned with atropine, after which inflation of the chest still caused a fall of pressure, but without slowing of the heart. The fall of pressure must be in some degree independent of vagus irritation, which, however, usually accompanies it.

15. It only remains to be considered whether the slow action or temporary stoppage of the heart with great fall of pressure produced by vagus irritation is, in itself, an element of danger in chloroform administration, and if it is not, wherein the danger actually lies.

16. The experiments in which deliberate irritation of the vagi was carried on during anæsthesia, show unmistakably that irritation of these nerves diminishes rather than enhances the danger of anæsthetics. The effect

upon the heart is never continuous, and as the vagus becomes exhausted, or when the irritation is taken off, the blood pressure rises again, as it does when the same result is produced by asphyxia. The slowing of the heart and circulation which is produced by irritation of the vagus by any cause, such as holding the breath in chloroform administration, retards the absorption and conveyance of chloroform to the nerve-centres, just as holding the breath, whether voluntary or involuntary, prevents chloroform from entering the lungs; and of itself, slowing, or temporary stoppage of the heart in chloroform administration, is not dangerous.

17. To answer the second part of the last question in paragraph 15 is easy enough, if it is kept in mind that the effect of vagus irritation upon the heart is never continuous; and in chloroform administration, as the pressure rises again after the slowing of the heart and temporary fall of pressure produced by any form of asphyxia, violent respiratory efforts with bounding heart's action lead, as in the case of struggling, to a rapid and dangerous inhalation of chloroform, and consequent rapid and dangerous decline in blood pressure. It is, in fact, the temporary exhaustion of the vagi after stimulation that is to be feared, and not the actual stimulation, as long as it is continued.

18. In accordance with this fact it will be found that in chloroform administration neither holding the breath, even if involuntary, nor vagus inhibition can be kept up beyond a certain time; and if the chloroform is not removed from the face, one or both of two things may happen: (*a*), When the animal breathes again, it takes deep and gasping inspirations, the lungs become filled with chloroform, and an overdose is taken in with extreme rapidity; (*b*), when the restraining influence of the vagus is taken off the heart, through the irritation ceasing or the nerve becoming exhausted, the heart bounds on again, and the circulation is accelerated in proportion. The blood then becomes quickly saturated with chloroform, and an overdose is at once conveyed to the nerve-centres. The theory which has hitherto been accepted is, that the danger in chloroform administration consists in the slowing or stoppage of the heart by vagus inhibition. This is now shown to be absolutely incorrect. There is no doubt whatever that the controlling influence of the vagus on the heart is a safeguard, and that it is the exhaustion of the nerve which is dangerous.

19. It can be readily understood how a condition in which the pulse is rapid and bounding, with high blood pressure, leads to more rapid absorption of chloroform into the lungs, and a more rapid propulsion of the chloroformed blood to the medulla oblongata, and consequently to a more rapid paralysis of the respiratory and vaso-motor centres, and precipitous fall in the blood pressure. Such a condition is produced in some cases by ether, or by division of both vagi, or by a full dose of atropine. Not only is the poisoned blood carried more swiftly to the vital centres in these cases, but added to this there is the fact that, as the heart is already doing its utmost before the chloroform is given, it is unable to stave off by increased work the fall in pressure that occurs when the vaso-motor centre is paralyzed. On the other hand, it seems clear from Experiment 92 that the direct action of chloroform upon the heart's substance is not the cause of the fall of pressure that occurs when it is inhaled.

20. In Experiment 92, repeated injections of 20 minims of chloroform were made into the jugular vein, and its effect was not to paralyze the heart, but to produce anæsthesia and a gradual fall of blood pressure, exactly as if the chloroform had been inhaled. In Experiment 72, after a considerable amount of ether had been injected into the jugular vein, and a bounding condition of pulse had been produced, the effect of injecting chloroform into the jugular was much greater, and the fall of blood pressure much more rapid and dangerous than in the case where chloroform alone was injected. Granting, then, the truth of Minger's conclusions from experiments on the frog's heart (which have not been repeated and confirmed by the commission) that chloroform has a gradual paralyzing effect upon the heart's tissue, we must conclude that such an effect, in the degree in which alone it could occur in the practical inhalation of chloroform, would rather be a source of safety than of danger.

21. The committee discussed the advisability of cutting the vagi some time previously to experimenting on the blood-pressure with chloroform. The effect of this procedure is to cause continuous rapid action and tendency to exhaustion of the heart, as well as to degeneration of the terminal branches of the nerves in the heart if the animal live sufficiently long.

Such experiments might be of some interest theoretically, and also have had a practical bearing upon the condition of the heart in certain cases of chronic alcoholism; but the committee decided not to perform them, as it considered the end to be gained did not justify the pain they would have inflicted.

22. In Experiment 178, the case of a dog that had had morphine, remarkable slowing, and even temporary cessation, of the heart's action occurred again and again at the same moment as the respiration stopped; but the heart invariably recovered itself, and began again to beat regularly, before any steps were taken to restore the animal, and without any respiration occurring. We find in this case that it was possible to restore the animal even after unusually long intervals had been allowed to elapse between the cessation of the natural and the commencement of the artificial respiration. The failure of the heart, if such it can be called, instead of being a danger to the animal, proved to be a positive safeguard, by preventing the absorption of the residual chloroform and its distribution through the system.

23. The effect of artificial respiration after the natural respiration has ceased, is to cause an alternate rise and fall of small amount in the blood-pressure, the trace thus formed upon the drum being a coarse imitation, altered somewhat by the shaking of the table, of the natural respiratory curve. The difference consists chiefly in the fact that the artificial rise always coincides with expiration or compression of the chest. After artificial respiration has been continued for a certain time, the blood pressure begins to rise again, and a little later natural respiration returns.

24. The effect of artificial respiration in restoring an animal after the respiration had stopped was always marked. In a few exceptional cases, such as Experiment 159—a phosphorus dog—and Experiment 142—a horse which had an enormous overdose, although the artificial respiration was commenced as soon as possible after the breathing was noticed to have stopped, it was not successful.

25. Complete stoppage of the respiration always means that an overdose has been administered, and the overdose may have been so great as to produce a very prolonged after-fall of blood pressure, and may thus render restoration impossible. As it is impossible to say whether, after chloroform has been pushed and then discontinued, the respiration will be restored spontaneously or not, so it is never in any case certain that artificial respiration will restore the natural respiration and blood pressure, no matter how soon it is commenced after the respiration stops. A great deal depends upon the amount of the after-fall; in some cases, even after the respiration has been restored, the pressure continues to fall and respiration again ceases, and artificial respiration then fails. We thus find respiration restored by artificial respiration while chloroform is still being absorbed, and this tends to show that artificial respiration does not merely pump the chloroform out of the blood, but exerts considerable influence in exciting the natural respiration.

26. The time which elapses before artificial respiration succeeds in restoring natural respiration varies very greatly. In one case, Experiment 116, it was continued for eleven minutes before the first natural gasps commenced. This period is undoubtedly prolonged in some cases by a condition of physiological apnœa, which renders it unnecessary for the animal to breathe. Consequently, whenever the pressure rose considerably during

artificial respiration it was stopped, and the animal then generally breathed after a few seconds.

27. The time which may be allowed to pass with impunity before commencing artificial respiration also seems to vary considerably. This point was not particularly attended to in the manometer experiments, except in Experiments 162 and 178, which were instituted to test the truth of the opinion formed by the sub-committee, that morphine had some slight action in impairing the efficiency of artificial respiration. In these cases the commencement of artificial respiration was postponed for more than two minutes after respiration ceased, and was successful; but this is certainly far above the average interval that can be allowed with safety. The success of artificial respiration in restoring the blood pressure is in some cases very remarkable; *vide* especially Experiment 40, in which the heart had apparently ceased beating, and the dog was believed by everyone present to be dead, and yet recovered with artificial respiration. The success in this instance is due to the fact that chloroform had only been administered for a few seconds, and that the depression was the result, not of continuous chloroform administration until respiration ceased, but of a long and severe after-fall.

28. It corresponds to those cases which are so often reported, in which dangerous failure of the heart is said to have occurred some minutes after the administration of chloroform had been discontinued, and which are sometimes restored, and sometimes not, by artificial respiration. There is nothing at all sudden about the failure of the heart in these cases, but the attention of the chloroformist, which has been wandering, is suddenly called to the fact that the patient is apparently dead. When the animal was really dead, it was found in some cases that artificial respiration still maintained a small amount of mean pressure in the manometer. In others the pressure seemed to fall to the zero line between each compression of the chest.

29. The dangers of too vigorous artificial respiration were illustrated in some of the accidental deaths. In one case the liver was badly ruptured, and in another the pleural cavity was full of blood. In these cases—Experiments 80, 92, and 103—rhythmical movements of the diaphragm were noticed after the heart had ceased beating and after the chest had been opened. It is remarkable that in two of these cases the splanchnic nerve had been divided. The third was a case in which chloroform had been injected into the jugular vein, and in this case there was a synchronous movement of the jaw as well. In all, death and stoppage of the heart had occurred gradually, and in Experiment 103 the heart was still irritable. These movements cannot be called respiration, though the last gasp of a dying animal, that ineffective jerk of the diaphragm which is such a fatal symptom, is very likely in many cases a movement of the same character. Similar movements, which were continued much longer, occurred in Experiment 104, after the thorax was opened, while the heart was still beating. Still more remarkable convulsions of the muscles of the jaws, ears, and forefeet occurred in Experiment 167, in the case of a dog that had been poisoned with nicotine. These movements continued at regular intervals for more than ten minutes after death, and were sufficiently forcible to jerk the handles of a pressure-forceps, fixed on the end of the tongue, off the table at each spasm. In a rabbit, in Experiment 153, the auricles of the heart continued to beat rhythmically for three hours after it was supposed to be dead from chloroform and its thorax had been laid open. Irritability of the heart after death was noticed in many cases, but seemed to be most marked in cases where ether had been used.

30. Chloroform injected into the heart through the jugular vein did not cause clotting of the blood, as was the case when ether was injected.

31. In the course of the experiments of the committee various drugs were administered in order to ascertain if they had any effect in modifying the action of chloroform. The result showed that none of them had any effect in preventing the typical descent of the blood pressure that occurs when chloroform is inhaled. Atropine, when given in a dose sufficient to paralyze the vagi, of course prevents the action of those nerves in asphyxia, and by increasing the action of the heart it appears to cause a more rapid descent in the blood pressure when chloroform is inhaled, as has been already explained. Morphine appeared, in Experiment 162, to render the rise in blood pressure, that occurred when the chloroform was discontinued, slower and less complete, and to bring about a more or less permanent condition of anæsthesia. It may be noted that the animal used in this was a monkey; and in other experiments with monkeys, when no morphine had been given, it was remarked that the animal, after a few inhalations of chloroform, would often lie quite quiet, in a state of semi-insensibility, for a long time without further inhalations; still this condition was much more marked in Experiment 162 than in any of the others. No action of this kind was noticed in the dog in Experiment 178, but other experiments (90 and 94) showed that pariah dogs are very indifferent to the action of morphine, and it is probable that the dose of morphine in this case was insufficient to bring about the condition noted in the monkey. The peculiar behavior of the heart in Experiment 178 was not the result of the previous administration of morphine, for a similar phenomenon had occurred in other cases (49 and 60) in which no morphine had been given. Experiments 162 and 178 prove conclusively that morphine had no effect in shortening the period that may be allowed to elapse between the cessation of natural respiration and the commencement of artificial respiration.

32. The other drugs used had no effect on the action of chloroform, except when their own special action became the leading feature in the case—as, for instance, during the vomiting from apomorphine (Experiment 104, Fick 9), or the convulsions produced by nicotine (Experiment 167).

33. In order to test the alleged danger from shock during chloroform administration, the committee performed a very large number of those operations which are reputed to be particularly dangerous in this connection—such as extractions of teeth, evulsions of nails, section of the muscles of the eye, snipping of the skin of the anus, etc. In many cases the operation was performed when the animal was merely stupefied by the chloroform, and not fully insensible. In such cases a slight variation in the blood pressure would sometimes occur, such as one would expect from the irritation of a sensory nerve or from the struggling that ensued; but in no case, in any stage of anæsthesia, was there anything even suggestive of syncope or failure of the heart's action. In thrusting a needle into the heart there was often a momentary but well-marked fall of the blood pressure; but even this was absent in all other injuries. If chloroform really had any power to increase the tendency to shock in operations, it is impossible to believe that it would not have been manifested, to some degree at least, in one or other of these numerous experiments. The commission was, however, not content with this negative result, and determined to ascertain the effect of direct irritation of the vagi during continued chloroform administration. The result of such experiments (65 and others) proved that inhibition of the heart's action prevented, rather than assisted, the fatal effects of prolonged chloroform inhalations. An animal that was put into a condition of extreme danger (from which it could only be restored by means of artificial respiration) by inhalation of chloroform for one minute, recovered spontaneously and readily after five minutes of chloroform inhalation, together with inhibition of the heart by electrical irritation of the vagus carried on simultaneously. In one of these experiments (117) chloroform was pushed for seven minutes; and during continued irritation of the vagus the animal repeatedly came round without artificial respiration. The danger really begins when the irritation is discontinued or fails to inhibit the heart, and thus enables the chloroform in the lungs to be rapidly absorbed and thrown into the system. The danger is certainly increased by deliberately pumping the chloroform into the lungs by means of artificial respiration, for animals in which this was

done, although they showed a tendency to recover when the chloroform and irritation of the vagus were discontinued, afterward died rapidly.

34. On another occasion, during Experiment 117, the animal was very nearly killed by a comparatively short inhalation of chloroform, owing to the electrodes becoming accidentally short-circuited and failing to keep up the irritation of the vagus. Something similar occurred in Experiment 177, the effect of the irritation of the vagus passing off while the chloroform was still being pushed, and thus putting the animal into a condition of extreme and unexpected jeopardy. Nothing could be more striking than these near approaches to accidental death from failure to irritate the vagus efficiently.

35. Other experiments were made to test the truth of the statement that chloroform increases the action of electrical stimuli applied to the vagus, and showed conclusively that it has no such effect. In one instance only the inhibition seemed to be intensified as the chloroform was commenced, and diminished when it was discontinued; but, apart from the fact that the supposed effect ceased much too suddenly, a repetition of the experiment, on the same and other animals, showed that there was in reality no such effect. The increased inhibition in this instance was due to the chloroformist compelling the attendant who was holding the electrodes to change his position, and thus making him unconsciously apply them more efficiently. When the chloroformist withdrew they were restored to their former position. This affords an instance of the care that has to be taken in making experiments, if one is not to be deceived.

36. To test the effect of shock due to vaso-motor change rather than to affection of the heart, Goltz's experiment on the frog was repeated on three dogs. In one there was slight lowering of pressure, which was not extensive, and in the others no effect was produced at all. Other operations which seemed likely to produce shock, such as violent blows upon the testicle, were singularly devoid of effect. Failing to lower the blood pressure by any of these methods, recourse was had to section of the splanchnics; but the low condition of blood pressure which this produced, appeared, like stoppage of the heart from vagus irritation, to be a source of safety rather than of danger during chloroform administration. In this connection Experiment 111 may be studied. There was not much external hemorrhage, but the splanchnics were divided—a proceeding which, as is often said, bleeds the animal into his own vessels. The pressure was after this extremely low, but chloroform was repeatedly given and various other actions taken, and then chloroform had to be pushed on a saturated sponge enclosed in a cap for eleven minutes before respiration ceased.

37. The conclusion, then, is this: Chloroform has no power of increasing the tendency to either shock or syncope during operations. If shock or syncope from any cause does occur, it prevents, rather than aggravates, the dangers of chloroform inhalation.

38. The experiments on dogs that had been dosed with phosphorus for a few days previously, show that the fatty, and consequently feeble, condition of the heart and other organs so produced has no effect in modifying the action of chloroform. The ease with which vagus irritation and the Glasgow trace could be produced in these animals, by even slight degrees of asphyxia, was very remarkable; but this was equally the case in dogs that had been given phosphorus only a few hours before the experiment, and whose organs were not yet fatty. Many of these cases were in the last stage of phosphorus poisoning, and several of their companions died, without any experiment having been performed upon them, before or on the same day as they died (*vide* the low state of blood pressure in Experiment 163). Numerous attempts were made in these animals to produce shock by operations in the recumbent and vertical positions, but without any more result than in those that were healthy.

39. The truth about the fatty heart appears to be that chloroform *per se* in no way endangers such a heart, but, on the contrary, by lowering the blood pressure, lessens the work that the heart has to perform, which is a positive advantage. But the mere inhalation of chloroform is only a part of the process of the administration in practice. A patient with an extremely fatty heart may die from the mere exertion of getting upon the operation-table, just as he may die in mounting the steps in front of his own hall-door, or from the fright at the mere idea of having chloroform, or of undergoing an operation, or during his involuntary struggles. Such patients must inevitably die occasionally during chloroform administration, and would do so even were attar of roses or any other harmless vapor substituted for chloroform.

40. The effect of hemorrhage was tested by opening the femoral artery and allowing a considerable quantity of blood (eight to twelve ounces) to escape. An immediate lowering of the blood pressure results, and this is very slowly recovered from. Such an accident, however dangerous it may be in itself, in no way affects the action of chloroform, except in so far that a patient who has been nearly bled to death would require less chloroform in his system to put him into a state of anæsthesia. The low condition of his blood pressure produced by the hemorrhage would tend to prevent the too rapid intake of chloroform, exactly as in the case of cutting the splanchnics (*vide supra*, subparagraph 36).

41. When the hind feet are lowered on to the floor so as to place the animal in the vertical position, a considerable fall of blood-pressure in the carotid artery occurs; but when the animal is replaced on the table in the recumbent position the pressure is fully restored. Various operations were performed on animals in the vertical position, but in no case was anything resembling dangerous shock produced. Inversion of the body, so that the animal stands on its head, has exactly the opposite effect, the pressure rising in the carotid artery, and again falling to its former state when the animal is replaced in the horizontal position. Inversion of the body failed to restore an animal that was in the last stage of chloroform poisoning, though it raised the pressure in the usual way as long as it was continued. The change in the pressure of the blood of the carotid, which occurs when the position of the body is changed, appears therefore to be due simply to the effect of gravity.

42. As regards the effect of chloroform upon different animals, it may be said to be the same as far as its anæsthetic action is concerned. There are certain peculiarities in its effect on respiration and circulation, connected with its local irritant action on the nostrils and fauces, which are interesting to notice. Thus, when concentrated chloroform vapor is applied to the nostrils of rabbits, they hold their breath, and the heart's action is slowed at once. This is always said to be due to reflex inhibition of the heart from irritation of the nasal branches of the trigeminus reflected through the vagus, and is by no means peculiar to chloroform, but is produced equally by any irritant vapor, such as ammonia or acetic acid.

43. In some dogs, and especially in those to which phosphorus had been given, stoppage of the respiration and slowing of the heart occurred immediately after the application of the chloroform to the face, or on forcibly pulling out the tongue, and this suggests that the mechanism of the cardiac arrest in them is precisely the same as it is in the rabbit. On the other hand, in rabbits, as in all other animals, it is possible to give chloroform so gently that no spasm of the chest occurs, no reflex effect is produced; and then the pressure falls in the same regular curve, and with the same succession of phenomena (anæsthesia, cessation of the respiration, and lastly cessation of the heart-beat) that was above described as typical of chloroform inhalation.

44. Goats have a great tendency to hold their breath while inhaling chloroform, and monkeys resemble dogs rather than rabbits, as when ammonia was held before a monkey's nose (Experiment 98) it did not cause immediate stoppage of the respiration and heart as it does in rabbits.

45. The experiments with ether show that it is impossible to produce efficient anæsthesia with this agent unless some form of inhaler is used which thoroughly excludes the air. If an ordinary cap containing a sponge saturated with ether is applied very closely to the face,

the animal generally holds its breath and struggles, and we at once get the fall of blood pressure and slowing of the heart that invariably occur under these circumstances. If the ether is continued in this way after the animal has recommenced breathing, a condition of semi-anæsthesia results in which the cornea is sometimes sensitive and sometimes insensitive, and the pressure rises and falls alternately to a slight amount and forms a wavy trace, which may be continued right around the drum without any particular change. As soon as the air is rigidly excluded, the pressure commences to fall gradually, exactly in the same way as with chloroform, and with the same succession of phenomena, viz., first anæsthesia, then cessation of the respiration, then of the heart movements, and finally death. How far this is due to ether and how far to the results of asphyxia, it is impossible to say, but an exactly similar succession of events can be brought about by making the animal inhale carbonic acid gas alone.

46. If surgeons continue to be content with a condition of semi-anæsthesia, it can no doubt be produced with perfect safety, though with discomfort, to the patient, by ether held rather closely to the mouth. Such a condition of imperfect anæsthesia would never be accepted by any surgeon accustomed to operate under chloroform. If more perfect anæsthesia is required, it can be procured by excluding the air more rigidly, but then there is exactly the same danger as in giving chloroform. How very suddenly and rapidly the pressure may fall and death ensue, is well shown by Experiment 33. Ether injected into the jugular vein produces a fall of blood pressure and anæsthesia in the same way as chloroform does, but in all cases in which it was so injected large clots were found in the heart immediately after death. It is interesting to note that Claude Bernard seems to have formed a very similar opinion with regard to ether, as the following quotations from his work, entitled "Leçons sur les Anesthésiques et sur l'Asphyxie," published in 1875, show. The first quotation (p. 50) is as follows: "Aussi, un certain nombre de chirurgiens proposèrent-ils d'abandonner le chloroforme pour revenir à l'éther, dont l'usage paraissait moins à craindre. Aujourd'hui encore, les chirurgiens de Lyon emploient préférablement l'éther. On croyait le chloroforme plus dangereux que l'éther parce qu'il était plus actif; mais, en réalité, la fréquence relative des accidents par le chloroforme tenait peut-être tout simplement à ce que c'était cet agent anesthésique qu'on employait dans l'immense majorité des cas. Plusieurs discussions ont été provoquées par les partisans de l'éther, surtout par les représentants de l'école de Lyon, et il a été constaté que l'éther, lui aussi, avait produit un certain nombre d'accidents mortels. Les deux agents anesthésiques usités peuvent donc, l'un comme l'autre, entraîner quelques risques de mort, et la chirurgie humaine a conservé presque partout le chloroforme, dont l'action est plus rapide et plus complète." The second quotation, to be found on p. 101 of the same work, runs: "Quant à l'éther et au chloroforme, leur action est à peu près la même au point de vue physiologique, sauf une différence d'intensité en faveur du chloroforme, ce qui nous fera généralement employer ce dernier corps de préférence à l'éther." *Beaumont Small.*

CHORDITIS TUBEROSA (*Trachoma of the Vocal Bands*). This peculiar laryngeal disorder, which is always associated with catarrhal inflammation of the entire larynx, is characterized by the formation of a small whitish nodule upon one or both of the vocal bands.

It is of special interest to the laryngologist because it occurs almost entirely in public speakers, singers, and actors. It always produces some degree of impairment of the voice, and, as it is a lesion which it is difficult to eradicate, it is well to appreciate its existence and treat it intelligently. Not much has been written about it. Most authors have been satisfied with brief mention of this condition as one of the manifestations of chronic catarrhal laryngitis.

PATHOLOGY.—Türck's[1] description of this lesion, to which he first gave the name "chorditis tuberosa," is the most comprehensive. Almost every author of recent years refers to Türck's article when writing of the pathology and etiology of this disease. Türck had noticed four cases of this peculiar inflammation of the vocal bands in singers, and he gives this description of the appearance of the larynx: "Midway in the upper plane of the bands there is a peculiar uneven surface, and, in addition to redness and swelling, some white opaque spots as large as poppy-seeds." These white spots, he says, become more noticeable as the general congestion subsides. He believes this peculiar lesion to be due to inflammation of the mucous glands.

Von Ziemssen,[2] speaking of the pathological changes of the vocal bands occurring in very protracted cases of chronic catarrhal laryngitis, says: "There is sometimes a roughness of the surface, which seems to be due to a partial *dermoid metamorphosis* of the mucous membrane — a condition called chorditis tuberosa by Türck." Wedl,[3] who examined specimens from a number of trachomatous vocal bands, found only connective-tissue hypertrophy with heaps of nuclei. Bosworth[4] says: "The pathological lesion is probably somewhat analogous to pachydermia, with the addition of a certain amount of connective-tissue hypertrophy;" and Sir Morell Mackenzie,[5] in a very brief description, says: "The lesion appears to consist in a hypertrophy of the connective tissue and a proliferation of its nuclei."

It is somewhat difficult to determine whether Virchow[6] is not describing the same pathological condition in his article on "Pachydermia of the Larynx." Certainly the appearances of the vocal bands in the earliest stages of pachydermia, as Virchow describes them, are quite similar to the nodules of chorditis tuberosa. Later, the infiltration and swelling are much greater in what he designates pachydermia than we see in chorditis tuberosa. He says the swelling is at first localized in the middle of the vocal bands. There are raised points with tissue-thickening about them, the raised points being the swelling of the squamous epithelium and the papillæ. This condition he believes to be due to long-continued congestion—a hyperplastic process, not an irritative one. He thinks it cannot consistently be called a chronic catarrh of the larynx, as there are neither mucus nor pus-corpuscles.

We believe that the essential pathological change in pachydermia laryngis is in kind like that found in trachoma of the vocal bands, but carried much farther from the normal condition; — pachydermia, as Virchow says, "occurring in aged drinkers, and caused by shouting." In an illustration of an extreme case furnished by Ingals,[7] in his article on "Trachoma of the Vocal Chords" (Fig. 68), we see a condition very similar to Virchow's pachydermia laryngis, and a much more advanced stage of disease than we have ever witnessed in chorditis tuberosa. We think mild cases of pachydermia may closely simulate extreme cases of trachoma, but the thickening extending both above and below the vocal bands, and forming polypoid enlargements, as Virchow pictures the later lesions of pachydermia, are not seen in chorditis tuberosa. The writer has had sections from two nodules which were removed from the vocal bands of different patients examined, and the result was the same in both instances: both specimens showed the result of simple inflammatory changes in the hypertrophy and increased number of the small round cells and connective-tissue corpuscles. It is essentially a hyperplastic process due to long-continued irritation and congestion of a moderate grade.

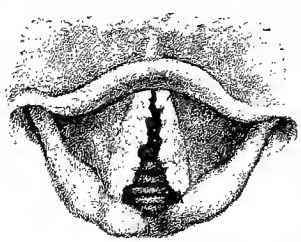

FIG. 68.

ETIOLOGY.—While it is undoubtedly true that a chronic catarrhal laryngitis is a predisposing factor in the causa-

tion of these peculiar nodular formations of the vocal bands, yet the exciting causes to be mentioned have a much more important bearing. The description of chorditis tuberosa should not be buried in a general article on catarrhal laryngitis, as it deserves separate treatment, by reason of its special etiology. The amount of the general catarrhal inflammation in these cases is not excessive, while the pathological changes of the vocal bands are out of proportion to the general catarrh.

The essential exciting cause of chorditis tuberosa is excessive use of the voice, and the lesion usually appears in singers. During the last two years I have seen eight cases of chorditis tuberosa. Six of these cases were in singers; the remaining two cases were in people who used their voices more than in ordinary conversation, one a Hebrew, who read aloud some religious ceremony every week, and the other a foreman of a large number of laborers, who was in the habit of shouting to his men. The six singers were all women and sopranos. It would be interesting to know if any cases of chorditis tuberosa have been seen in people who do not use the voice except in ordinary conversation. I have never seen such a case. This may be explained by the fact that probably none but singers, actors, public speakers, etc., go to a physician on account of the moderate hoarseness which the nodule on the vocal band produces. It is my belief, however, that this nodule is produced by excessive use of the voice in singing and public speaking, and that it is also largely attributable to *a faulty method of singing or an improper manner of using the voice.* It is a significant fact that six of the eight cases observed were singers and sopranos, conditions, as we know, requiring the highest tension and the most rapid vibration of the vocal bands. In writing the histories of these six cases, some attention was paid to the manner in which the voice had been trained, and it seemed to me significant that two of the patients were in the same class at a grand conservatory of music where only the "true Italian method was taught." During vocalization in both of these cases, as the scale was ascended the epiglottis was carried farther downward and backward with each note and the larynx was compressed more and more. One of these women could sing only a short time without becoming quite hoarse. After changing her teacher and using her voice in a different manner, she was able to sing at a theatre every night, although there is still some nodular enlargement on one of the bands.

One of the patients—an operatic singer of great reputation—stated the pathology of the condition known as "chorditis tuberosa" quite accurately when she said, after the laryngoscopic appearances had been described to her, "Why, I should say I had corns on my vocal bands"—the "dermoid metamorphosis" of Von Ziemssen.

These nodular enlargements are produced by the rapid vibrations of the vocal bands, weakened by catarrhal inflammation and over-use. After the chords become congested and thickened the friction of one band against the other is probably a contributing factor, just as the outer layers of the skin of the foot become hypertrophied by the friction of an ill-fitting shoe. This is especially true when the tension of the chords is unevenly controlled. While some congestion of the vocal bands, incident to the general catarrh, precedes the nodular swellings, the larger portion and the general thickening of the bands follow the formation of the nodules on the chords and are caused by the nodular enlargement. The nodular swellings are therefore in a sense primary, and the other changes in the bands secondary.

The irritation caused by the constant friction of the nodular enlargement with the opposite band, and the extra exertion necessary to produce a true tone in singing or a clear voice in speaking—these cause congestion with hyperplastic changes, and eventually an exhaustion of the adductors and tensors of the bands.

Symptomatology.—The nodular enlargements may be situated upon one or both bands. In five of the eight cases I have seen, the nodule was on the left band. It is usually located a trifle more anteriorly than midway between the vocal processes and the anterior insertions of the vocal bands, and it may be on the upper surface of the chord or upon its free margin.

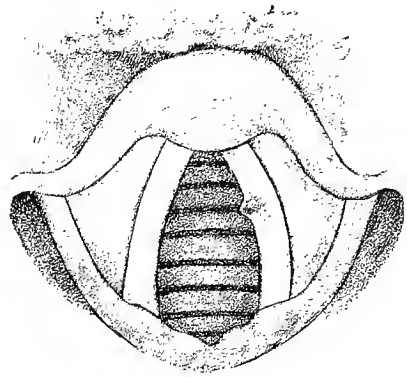

Fig. 69.

A nodular enlargement of one band, if the voice is persistently used in singing or public speaking, will in time produce some alteration in the tissue of the other band at the point of contact. Sometimes there is an appearance of depression in the second vocal band just opposite the nodule.

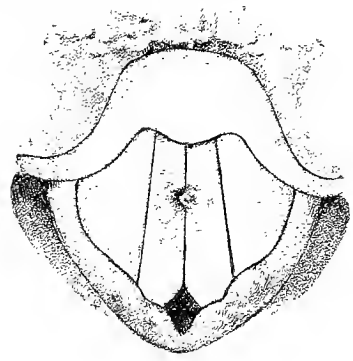

Fig. 70.

If this depression is examined carefully, the mucous covering will present a roughened appearance, a callous spot which has been produced by the protruding point on the opposite band. This callous depression is really raised above the normal surface of the vocal band; but a concavity exists because the edges about the depression are elevated to a still greater degree. After the nodule has existed for some time the depression on the second band is sometimes filled, and later gives place to a second nodule. Two nodules are now seen striking against each other, and the bands are just so much more prevented from approximating during phonation. If these nodules are not removed, and if the person is allowed to continue singing, the irritative friction and the increased effort of the intrinsic laryngeal muscles necessary to bring the bands together cause congestion and thickening of the entire substance of the bands. If a very careful examination of one of the nodules is made in its earliest stages, the mucous membrane covering it will seem to be unaltered, and the millet-like nodule seem to be wholly situated in the substance of the band. It requires strong illumination to correctly appreciate the exact amount of congestion and swelling of the vocal bands. The nodules in this disease are, when first formed, pearly white, but later become a dirty gray. The color of the nodule, however, depends much upon the color of the adjacent vocal bands. When the entire band is congested and thickened, the nodule can be seen with difficulty; when the congestion of the band disappears, the nodule stands

out prominently. With poor illumination the vocal bands will seem to be nearly normal; a better light will reveal enlarged capillaries, running over the surface, and in the substance of the vocal bands, which in color vary from a gray to a pale red. The location of the nodule may always be easily discovered, because the secretions stick to this part of the chord, and when the chords separate during inspiration, a thread of mucus may be seen, stretching across from the nodule on one chord to the point of contact on the opposite chord. The degree of approximation of the bands depends upon the size of the nodule and upon the strength of the adductors of the vocal chords. The size of the interval between the chords varies from day to day, because the nodule changes in size rapidly without apparent cause (Fig. 71). I have seen a nodule develop in forty-eight hours, on a vocal band long affected, because of over-

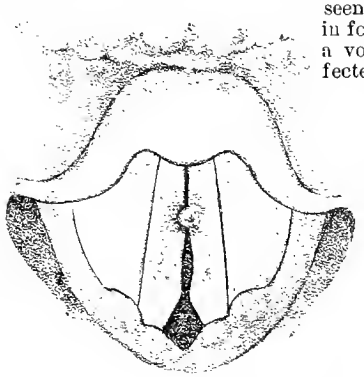

FIG. 71.

singing during a single evening. The chords approach each other more closely in front of the nodule than behind it. The failure of the bands to meet each other throughout their entire length occasions "phonatory leakage," and impairment of voice, which is about the only symptom of this affection.

The degree of hoarseness will depend, not only upon the size of the interposing nodule and the amount of secondary inflammatory changes in the vocal bands, but also upon the skill with which the vocal apparatus is employed. We all know how well some singers vocalize with greatly altered vocal bands.

DIAGNOSIS.—The single pearly nodule, as large as a pin's head, will be, in the early stages, easily diagnosed from other lesions of the vocal bands. When the bands become congested and thickened, a little more care will be required, but the diagnosis is never difficult.

"Chorditis tuberosa" should not be confounded with the uneven surface of the vocal bands seen in long-standing cases of simple chronic chorditis, where the vocal apparatus has been abused for many years, and strong astringents or caustics have been so frequently applied to the larynx that little normal mucous membrane remains. Chorditis tuberosa should be differentiated from the cicatrices following tubercular and syphilitic ulcerations, or from granulation tissue springing from the base of ulcers, and also from benignant growths attached to the vocal bands.

TREATMENT.—In no laryngeal disorder must the treatment be more painstaking. Skilful manipulation will be required to eradicate it. These cases should be treated as early as possible before the second band has been injured by the protruding nodule on its fellow, and before the bands have become congested, thickened, and stiffened, and the vocal tensors exhausted beyond recovery. They should not be allowed to sing or to use their voices except in quiet conversation. The voice should be rested, not only until the nodular enlargement has disappeared, but until congestion has abated and the muscular tone of the larynx has been restored.

It is hardly necessary to say that the nose and pharynx should be put in good condition. Colds in the head and inflammation about the pharynx always aggravate this condition of the vocal bands. The condition known as pharyngitis sicca bears a specially close and injurious relation to a trachomatous vocal band, and every effort should be made to keep the pharynx moist while treating the larynx.

The local remedies are not many which are of use in the judicious treatment of chorditis tuberosa. The nodule must be eradicated first of all. Time can be saved, in rare instances where the nodule is large enough, by snipping it off to the plane of the free edge of the band. I have twice used successfully a small, circular, snap, guillotine-knife, the circle about a quarter of an inch in diameter.

With the aid of cocaine this circle can be placed around the nodule and the band pressed toward the lateral wall of the larynx before the knife is sprung. This instrument can be used more delicately than a laryngeal forceps, and with less damage to the bands. After the nodule has been cut off, a solution of zinc chloride or of silver nitrate, from thirty to sixty grains to the ounce, may be

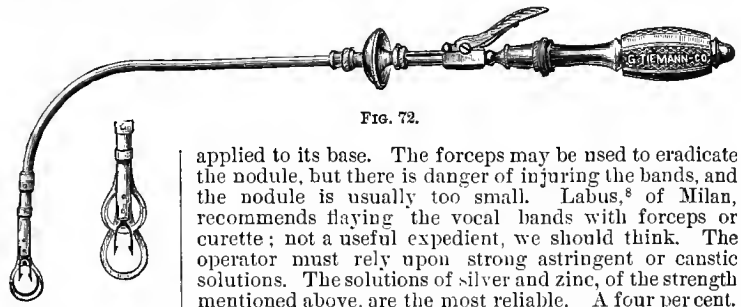

FIG. 72.

applied to its base. The forceps may be used to eradicate the nodule, but there is danger of injuring the bands, and the nodule is usually too small. Labus,[8] of Milan, recommends flaying the vocal bands with forceps or curette; not a useful expedient, we should think. The operator must rely upon strong astringent or caustic solutions. The solutions of silver and zinc, of the strength mentioned above, are the most reliable. A four per cent. solution of cocaine, sprayed into the larynx, will enable the operator to apply the solution to the nodule alone, without touching the remainder of the band. Slight inflammatory action follows this application, which disappears in forty-eight hours. This should be remembered when treating a patient who is obliged to sing at the earliest possible moment. Mackenzie recommends applications of ferri perchlor., ʒ ij. ad ʒ j. Chromic acid crystals may be applied to the nodule by means of some form of the guarded or concealed laryngeal applicator. This application should not, of course, be made until the movements of the larynx are controlled by cocaine. A week or ten days must elapse before the larynx recovers from this application.

A fine-pointed galvano-cautery electrode, exposed not more than one-eighth of an inch, could, in skilful hands, be applied to the nodule as easily as the acids. After the nodule has been nearly eradicated, its return may be prevented by weak astringent solutions sprayed into the larynx, such as solut. argent. nit., gr. v. ad ʒ j.; zinc chlorid., gr. x. ad ʒ j. A very weak solution of cocaine (one per cent.) may be with benefit sprayed into the throat just before the astringent sprays are used. When the entire substance of the band is congested and thickened, absorption can sometimes be effected with a solution of iodol or iodoform in ether (ʒ j. to ʒ j.). I have found that oily sprays are of little value and apt to be drying. It has been mentioned that the adductors and tensors of the vocal bands become fatigued by persistent singing in patients who have trachomatous bands, as much more than the usual muscular strength is required to bring the bands together, on account of the interposing nodule; hence, after the nodule has been removed, the galvanic or faradic current should be employed. I prefer the faradic; the two electrodes may be placed one on each side of the thyroid cartilage, or one pole may be applied to the arytenoid cartilages. The benefit seems to be about as great when the poles are applied externally.

Dr. Gautier's method of applying the galvanic current, called "interstitial electrolysis," might be useful in removing the nodules. He applies a copper electrode positive pole, insulated up to near its tip, to the growth, the negative sponge electrode to the back or chest; a weak current is used—from five milliamperès up. The action of absorption is based upon the fact that oxychloride of

copper is formed at the positive pole, which permeates and causes absorption of the growth. The author says the action produces no burning or destruction of tissue, since the energy of the current is expended in forming the copper salt.

Finally, after the bands have been made as nearly normal as possible, we should insist that our patient, if he is a singer, put himself under the instruction of a proper teacher. This advice is imperative if we would cure this class of patients. A faulty method of using the voice will bring back in a short time the catarrhal conditions and the nodular enlargement.

The points I would place emphasis upon are these:

1. That while chorditis tuberosa is in a sense one of the manifestations of a chronic catarrhal laryngitis, yet its real cause is excessive use of the voice.

2. That the nodule on the band is largely the primary lesion, while the other changes in the bands are secondary.

3. That this condition is almost always found in singers or public speakers, and is occasioned to a great degree by a faulty method of using the voice.

4. That chorditis tuberosa occurs more frequently in women than in men, and is seen most often in sopranos.

5. That a nodular enlargement will in time produce change in the second band at the point of contact; and,

6. That these nodules should be removed as early as possible. Singing should not be allowed until the bands are normal, and faulty methods of using the voice should be corrected by proper teaching. *Clarence C. Rice.*

CHROMIC ACID. A new use of this escharotic was brought to the notice of the profession by Dr. Edward Woakes, in *The Lancet*, June 21, 1890. He there advocates its use in the treatment of cystic goître, ranula, and other cysts. The cyst or sinus is to be opened and thoroughly evacuated and washed, and all hæmorrhage checked; a saturated solution of the acid is then applied to the secreting surface with a chromic-acid carrier, and the patient kept at rest for a few days. No severe reaction occurs and the cavity is rapidly obliterated. Repeated applications may in some instances be required, four or five days elapsing between each. It is recommended to apply this method of treatment to all sinuses and cavities with a secreting wall. There does not seem to be any danger of absorption of the drug, as it coagulates the albumin of the tissues and forms a thick, dense membrane. Dr. Woakes says "repeated observation points to a complete and rapid amalgamation between the tissues and acid to such an extent that thereafter neither the one nor the other retains its former character." All hæmorrhage should be carefully checked, as it neutralizes the acid and prevents its action on the cyst-walls.

This acid has also been selected to destroy the false membrane in diphtheria. A forty per cent. solution is used and the membrane touched two or three times a day by means of a pencil. The applications are to be made with the greatest care, to avoid injuring the mucous membrane. It does not produce any inflammatory action and is painless. The false membrane alone is destroyed and the production of the toxic ptomaïnes arrested. In addition antiseptic spraying and constitutional treatment are also adopted. *Beaumont Small.*

CINNAMIC ACID. This acid is one of the numerous drugs introduced on account of its reputed value in the treatment of tuberculosis. It is produced by the oxidation of oil of cinnamon in air or oxygen; it also exists ready-formed in balsams of tolu and Peru, and in storax. It may be obtained by the following process: Old, hard balsam of tolu is reduced to powder and mixed with an equal weight of slacked lime; this mixture is boiled for some time in a large quantity of water, and filtered while hot. On cooling calcium cinnamate crystallizes. This is redissolved in hot water, digested with charcoal, and filtered and allowed to cool. The crystals are again dissolved in hot water, and an excess of hydrochloric acid being added, it is again allowed to cool, when cinnamic acid separates in a pure state.

It resembles benzoic acid and possesses many of its properties. It forms small white plates or needle-shaped crystals of perfect whiteness, without odor. It is insoluble in cold water; soluble in hot water, alcohol, and ether.

Cinnamic acid has antiseptic properties similar to salicylic and benzoic acids, and has been used to make antiseptic dressings of gauze, jute, etc.

Its use in tuberculosis has been recommended by Dr. A. Landerer, of Leipsic.

For pulmonary phthisis it is employed only by intravenous injections, the object being to bring the acid in direct contact with the diseased pulmonary tissue. A five per cent. emulsion of the acid is prepared, and from one and one-half to fifteen minims injected twice a week. The veins of the arm are selected. The part is rendered aseptic and the vessels distended by means of gentle pressure. After the injection the part is dressed with sublimate gauze and the pressure removed. No bleeding or inflammation follows the puncture. No immediate effects are produced by this medication, but in the course of a few weeks the sputum changes its color and loses its purulent character, the cough lessens, night-sweats cease, all disagreeable symptoms lessen, and the general health improves. It is advised to continue the treatment for at least three months.

In surgical tuberculosis the acid is injected into the diseased tissue. The injections are made deeply into the part, seven and one-half minims being used twice a week. In fistulous disease, injections of a five per cent. alcoholic solution were used. In lupus vulgaris each tubercle is to be injected with one or two drops of the solution. After the injections there appears redness and tumefaction, which subside in two or three days; the nodules gradually disappear and approach the normal skin in composition. The pain of the injection may be overcome by combining five per cent. of cocaine with the alcoholic solution. Dr. Landerer reports very favorable results from this treatment, but others have not as yet adopted its use. *Beaumont Small.*

CLUB-FOOT. From time to time cases have been reported to both prove and disprove each of the theories previously advanced as to the etiology of congenital club-foot, but no new facts have been added to our stock of knowledge.

TREATMENT.—The treatment consists in correcting the deformity, and maintaining the corrected position until there is no longer a tendency to relapse.

The treatment is commenced at the earliest possible moment, and the retentive treatment may have to be continued for years. Simpler means are always to be tried before the more radical operations are attempted, but the tendency of the profession is very decidedly in favor of rapidly correcting the deformity in place of gradual and prolonged stretching by complicated mechanical devices.

Of the braces used for gradually correcting the deformity by a leverage, or stretching process, none are more simple, and yet effective, than those for many years employed by Dr. Charles Fayette Taylor (Figs. 73 to 76). The sole-piece is of sheet steel, the upright a steel bar joined to the sole-piece by a strong rivet, allowing antero-posterior motion; the extent to which the toe is allowed to drop is regulated by a set screw. Sufficient straps are attached to retain the foot, and these are usually at the places shown in the illustrations. The cuts illustrate the manner of applying the adhesive plaster and adjusting the brace. It will be noted that the upright piece can be bent to exert any desired degree of leverage. This splint will be found of great service as a retention walk-

ing apparatus after forcible correction or operative procedures.

Forcible correction is accomplished by the hand in moderately severe cases in young infants, and by wrenching and crushing with various machines. The simplest

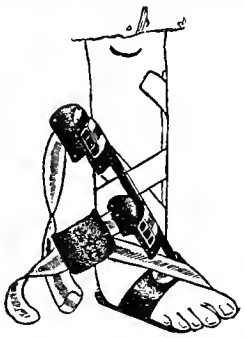

FIG. 73.

FIG. 74.

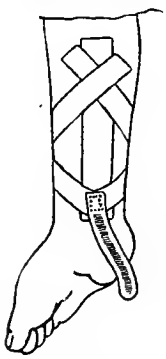

FIG. 75.

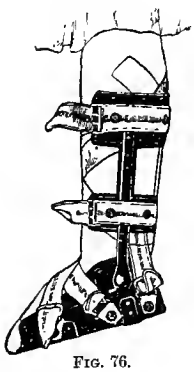

FIG. 76.

FIGS. 73 to 76.—The Taylor Club-foot Brace.

effective machine is the Thomas wrench, Fig. 77. It may be used as the primary procedure, or as secondary to operation. When used as supplementary to a cutting operation the patient is anæsthetized, and the attempt is made to fully correct the deformity at a single sitting.

One of the most powerful devices for forcible correction is Dr. Phelps's machine, Figs. 84 and 85. This machine Dr. Phelps uses only when the patient is anæsthetized, and generally, if not always, as a supplementary procedure to a cutting operation.

Forcible correction by machine should not be attempted in cases where correction can be accomplished by the hand. It may be employed with equal advantage after

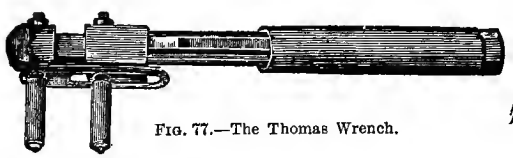

FIG. 77.—The Thomas Wrench.

subcutaneous and open incisions of the soft parts, and after the cutting operations upon the bones.

The choice between subcutaneous and open incisions for the division of the soft parts depends upon the skill of the operator, the severity of the deformity, and the care with which strict asepsis can be carried out. It surely requires more manipulative skill to thoroughly divide all of the shortened parts subcutaneously than openly, and in some cases a satisfactory subcutaneous division cannot be accomplished. In old and severe deformities much time is often wasted in futile subcutaneous operations. An open wound is certainly a safer wound than a subcutaneous one when infected. On the other hand, subcutaneous incisions to which no thought of asepsis has been paid beyond ordinary cleanliness rarely become infected; it is the universal rule that they heal without suppuration, while open incisions rarely escape infection unless treated with the most careful aseptic precautions at the time of the operation and at subsequent dressings, should such be necessary. Strict asepsis demands no little personal care as to the preparation of dressings in private practice, and, in the dressing of these wounds of the feet, demands at least one trusty assistant. Strict asepsis, it must be admitted, is not possible for very many

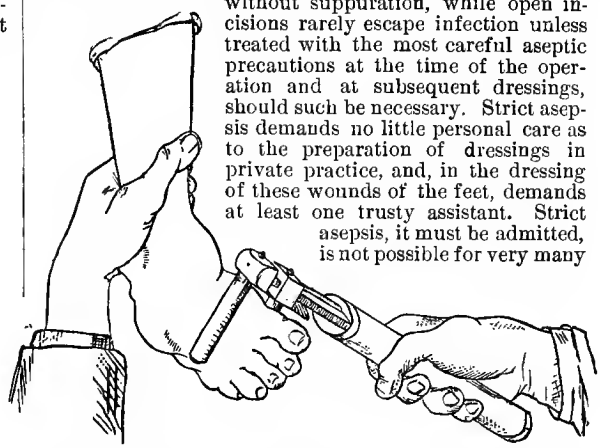

FIG. 78.—The Thomas Wrench applied to a Case of Talipes Equino-varus.

men who are called upon to treat deformed feet. I would not be understood as saying that in the hands of such the subcutaneous operation is the safer, for it is not, but it is reasonably safe, and if successfully performed will result in healing within three or four days as against as many weeks if the wound must heal by granulation.

Thomas's Method. — This method of stretching the foot into a corrected position differs from all other stretching methods for the cure of congenital varus. It takes a middle place between stretching by braces, which on the one hand exert "continuous

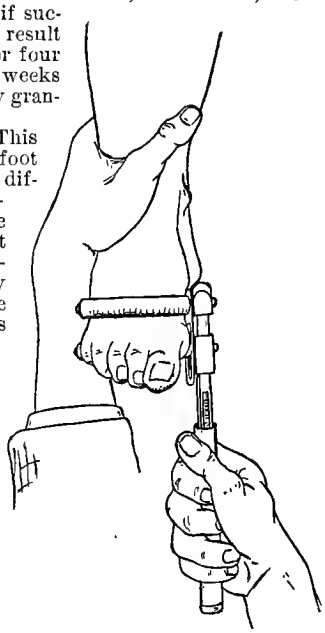

FIG. 79. — The Deformity Partially Corrected by the Wrench.

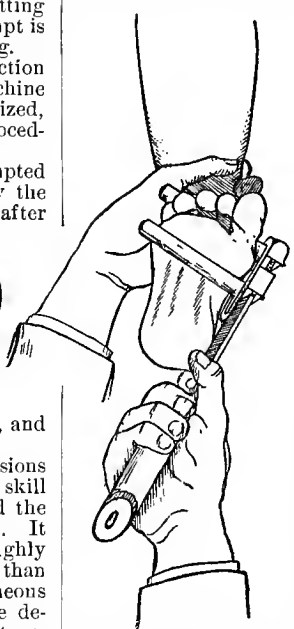

FIG. 80.—The Deformity Fully Corrected by the Wrench.

leverage," or "elastic traction," or "the weight of the body as a corrective force," and the machines which forcibly correct the deformity under an anæsthetic at a single sitting, on the other hand. By the wrench shown in Fig. 77, and applied in Figs. 78, 79, and 80, the foot is stretched, or "wrenched," or sprained to a degree just sufficient to abolish the resiliency of the shortened tissues. The foot is then retained in a simple metal brace (Figs. 81 and 82) until at the end of from two to six days the resiliency be-

gins to return and the foot tends once more to assume its old position; then the wrenching is repeated. These wrenchings are repeated every few days, the intervals becoming longer as the foot comes into a better position, until the deformity has been fully corrected, and shows no tendency to relapse.

Tenotomy.—In doing subcutaneous division of the shortened soft parts, surgeons for the most part proceed as follows:

For the ordinary form of congenital talipes equino-varus the tendo Achillis is first divided about an inch and a half above the point of its insertion. The patient lies on his face, the assistant puts the tendon on the stretch by flexing the foot, the skin is drawn somewhat to one side, and with a pointed tenotome a puncture is made at the side of the tendon, passing beneath it. With this same knife, or with a blunt pointed one in its place, the tendon is then divided by turning the edge of the knife toward the tendon, and moving it with a gently sawing motion. As soon as the assistant feels the snap of the divided tendon, he should instantly relax the flexion. When the cavity left by the incision has filled with blood, the operator attempts full flexion of the foot. In a certain number of cases this will not be found possible, and the choice then is between a section or a forcible rupture of the posterior ligament of the ankle-joint. Section of this ligament is accomplished by a spear-shaped tenotome passed through the middle of the tendo Achillis, then turned half around and swept from side to side. Most surgeons, however, prefer to rupture the ligament by the hand, the wrench, or some other mechanical device. Unless full flexion at the ankle joint be made possible before the anterior portion of the foot is subjected to operation, it will be found very difficult of accomplishment. The next step is a division of as much of the deltoid ligament as may be necessary, and such other shortened tendons as may be reached by the knife through the same incision. The foot being put on the stretch in the direction of outward rotation, a sharp, pointed tenotome is entered flat close to the anterior border of the inner malleolus with its back next the bone, and carried around under the tip of the malleolus. It is then removed and replaced with a blunt knife, preferably convex on the edge; the edge is turned toward the ligament, and as much of it divided as may be necessary. Through the same opening the tendon of the posterior tibial, and the anterior tibial, and astragalo-scaphoid capsule may be divided. By passing the tenotome somewhat deeper and close to the bone, the tendon of the long flexor of the toes may be divided. The tendon of the extensor of the great toe stands out prominently over the metatarso-phalangeal articulation, and here it is divided from within, outward, when required. The abductor of the great toe and the plantar fascia are divided just in front of the inner tuberosity of the os calcis. When all resisting bands that can be made out to the touch have been divided the foot should be forcibly overcorrected by the hand, or the wrench, or some other mechanical device, and should be retained permanently in that position. Strict asepsis should be practiced in these tenotomies, and the wounds sealed with collodion and a small bit of gauze. No permanent pressure should be made to check bleeding. If the bleeding is sufficient to demand pressure, a free incision should be made and the bleeding vessel ligatured. Pressure diminishes the quantity of plastic effusion, and may be the cause of a weak union between the divided ends of the tendons. Dressed without pressure, perfect union may always be confidently expected, no matter how far the cut ends may be separated. The method, formerly in general use, of leaving the foot in its deformed position for a few days until soft union between the divided ends of the tendons had taken place, and then gradually stretching this new material, may be held responsible for many cases of weak union, and even of non-union.

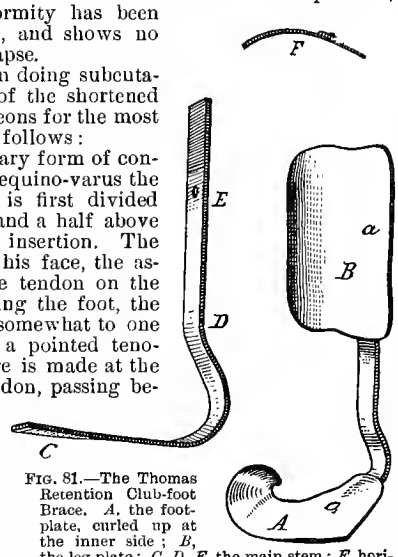

FIG. 81.—The Thomas Retention Club-foot Brace. *A*, the foot-plate, curled up at the inner side; *B*, the leg-plate; *C*, *D*, *E*, the main stem; *F*, horizontal section of leg-plate and main stem, showing the plate extending farther to the inner side of the stem than to the outer.

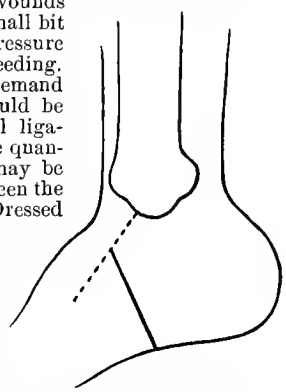

FIG. 83.—The solid line indicates the incision in Phelps's operation.

Phelps's Operation.—This consists in making an open incision commencing in front of the inner malleolus, and extending one-third the distance across the sole of the foot, and carried down to the neck of the astragalus, on its inner side. (Fig. 83.) Through this wound, the adductor pollicis, tibialis posticus, the plantar fascia, the flexor brevis, the long flexor tendons of the toe, and the deltoid ligament, all its branches, if necessary, can be cut. This is done after subcutaneous tenotomy of the tendo Achillis has been performed. Great force is then used by the machine shown in Figs. 84 and 85, to rupture the deep ligaments and super-correct the foot.

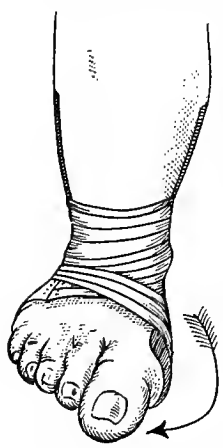

FIG. 82.—The Thomas Club-foot Brace applied.

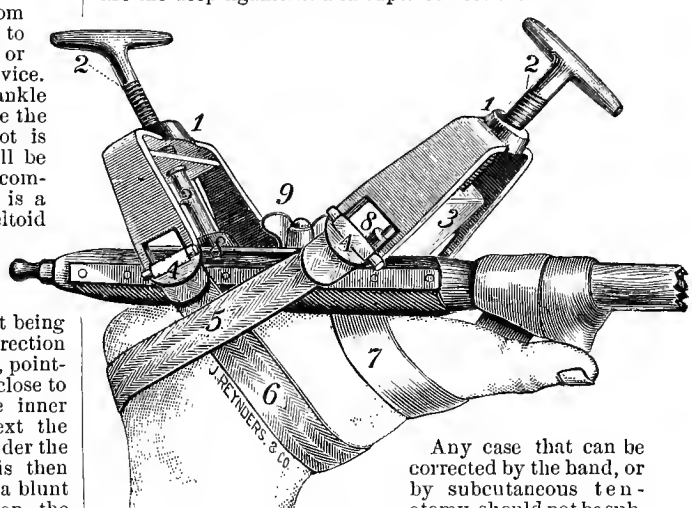

FIG. 84.—Phelps's Machine adjusted.

Any case that can be corrected by the hand, or by subcutaneous tenotomy, should not be subjected to Phelps's operation; and when the operation as described fails to easily supercorrect the foot, a linear osteotomy should be made through the neck of the astragalus. If this fails, a V-shaped piece should be removed from the os calsis, the point of the V meeting the linear osteotomy of the astragalus. This failing, the removal of the cuboid and scaphoid is indicated. And, as a last resort, Pirogoff's amputation should be resorted to.

The wounds of Phelps's operation are sutured or not, as may be possible, and dressed without drainage, with the aim to obtain blood-clot organization. The feet are dressed in the super-corrected position, in plaster-of-Paris.

Phelps first operated in 1879, and to him more than to any other is due the credit of leading the way to perfect results in inveterate cases of club-foot.

Ridlon's Operation.—This is a modification of Phelps's operation, designed to avoid a tender scar on the sole of the foot. In Phelps's earlier operations, the incision was underneath the bones, closely hugging them. As these incisions are made, an assistant constantly keeps the parts on the stretch in the direction of correction of the deformity, and each part as it appears to resist the correcting influence is divided. When any considerable degree of equinus is present, the first incision passes beneath the

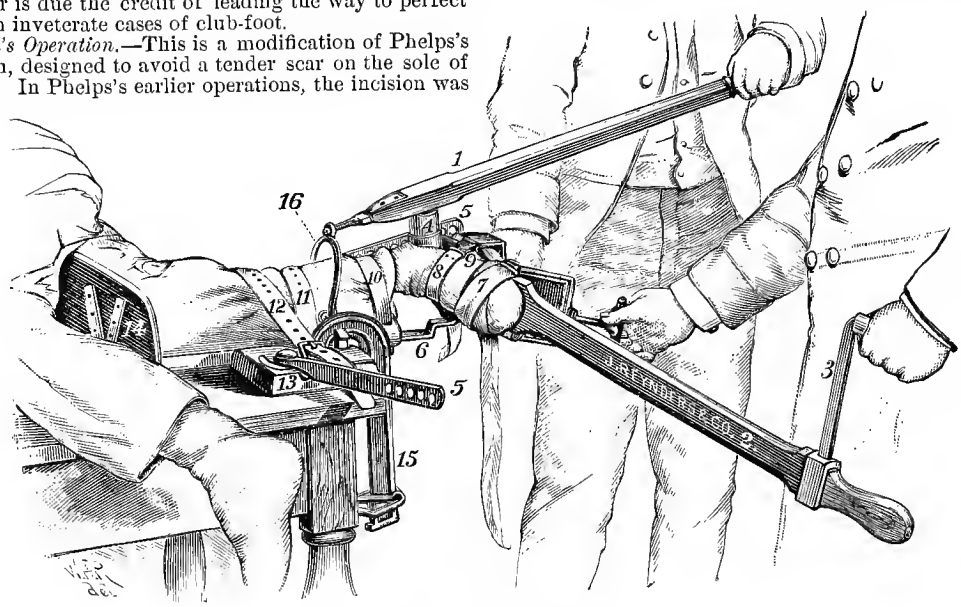

FIG. 85.—Phelps's Machine in Use.

carried two-thirds across the sole of the foot; at present it is carried but one-third that distance, and the objection to a tender scar holds less well than before the modified operation was devised.

The operation which bears the writer's name consists of an incision commencing on the dorsum of the foot just in front of the inner malleolus, at the point where the tendon of the extensor longus digitorum muscle crosses to the inner side of the foot; from here it is carried directly

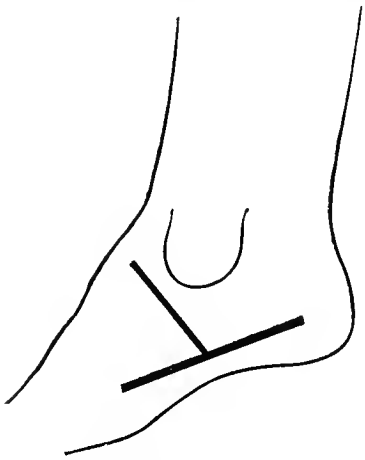

FIG. 86.—Ridlon's Operation; Lines of Incisions.

toward the sole, to meet near its middle a second incision made parallel with the sole from near the inner tuberosity of the os calcis to the middle of the first metatarsal bone, or beyond (Fig. 86). The plane of the first incision leads directly downwards to the bones; the plane of the second incision slopes upwards and outwards to reach the bones at their nearest border; thence it is carried anterior half of the inner malleolus, and in some cases beneath the whole of it. The deltoid ligament, and the tendons of the tibialis anticus, extensor proprius hallucis, extensor longus digitorum, extensor brevis digitorum, tibialis posticus, flexor longus digitorum, and flexor longus hallucis, are readily reached. From the second

FIG. 87.—*A.* Plaster-of-Paris imprint from a boy of eleven, after excision of the astragalus for resistant club-foot. *B.* Drawn from a photograph of a boy of eleven, after osteotomy of the neck of the astragalus for club-foot. (Bradford.)

incision the abductor hallucis, the plantar fascia, and any other resisting structure may be divided. By carrying the second incision in the plane directed, it will almost always be possible to avoid dividing the internal plantar artery and the nerve. The division of all tight bands having been made, the foot is overcorrected by the hand

or by the wrench. As in Phelps's method, we believe it better to divide the tendo Achillis and correct the equinus, rupturing, if necessary, the posterior ligament of the ankle-joint, before commencing the operation for correcting the deformity of the anterior portion of the foot. The dressings are the same as in the Phelps's operation, namely, suturing, in so far as possible without putting the parts at too great tension, and covering the wound with Lister protective and aseptic dressings, with the expectation that healing by blood-clot organization will take place. Over all is applied a plaster-of-Paris dressing with the foot in the supercorrected position. In inveterate cases where the foot cannot be easily held in the supercorrected position, operations on the bones are indicated as pointed out under Phelps's operation.

The principles, first clearly laid down, we believe by Phelps, must never be lost sight of: First, correct all cases possible by hand; second, correct all possible by subcutaneous incision; third, of the remaining cases, divide by an open incision all resisting soft parts, and with the hand or some mechanical device supercorrect the deformity; fourth, when this cannot be readily done, do a linear osteotomy of the neck of the astragalus, followed if necessary by cuneiform osteotomy of the os calcis; if this is not sufficient, enucleate the astragalus, or remove any bone or portion of bone which blocks the way; and if this is not sufficient, amputate.

Dr. Bradford has recently pointed out that in some cases there is elongation of the outer border of the os calcis and a consequent obliquity of the anterior (cuboid) articulating surface which can only be remedied by removing the wedge-shaped piece from its outer side just posterior to the cartilage. In the normal foot a line drawn antero-posteriorly through the centre of the heel and the centre of the front part of the foot meet to form a straight line (Fig. 87, B), while in the foot with a distorted os calcis, the lines meet to form an angle (Fig. 87, A). An imprint of a normal foot is seen in Fig. 89, and of a corrected club-foot in Fig. 90, while Fig. 88 shows a foot with a deformed os calcis which, after tenotomy, could readily be fully corrected, but which at once drops back into inversion because of the obliquity

FIG. 88.—Sole imprint of a case of club-foot corrected by tenotomy with inversion of the foot without contraction. (Bradford.)

FIG. 89.—Imprint of a normal foot. (Bradford.)

FIG. 90.—Imprint of a foot of a child six years old, treated when one year old, for congenital club-foot. (Bradford.)

FIG. 92.—Imprint of the same foot after operation. Osteotomy of the neck of the astragalus and os calcis. (Bradford.)

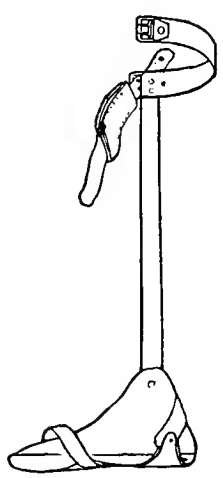

FIG. 93.—Judson's brace.

of the calcaneo-cuboid articulation. In these cases where distortion of the os calcis is present, correction by force, by tenotomy, by open incision on the inner side of the foot, and even by enucleation of the astragalus, fails to permanently remove the inward twist of the anterior portion of the foot. Figs. 89 and 90 show the improvement which may be gained in inveterate cases.

An imprint of the foot as shown in these illustrations will be found a most convenient guide and a valuable record. A sheet of paper is smoked over a piece of burning camphor, and after an imprint has been made by the patient stepping upon it, it is rendered permanent by pouring over it a little photographer's varnish. The composition of the varnish is: Gum sandarach, oz. 1½; alcohol, oz. 8; castor-oil, dr. 2. Mix.

Whatever method be employed to correct or supercorrect the deformity, it is but the first step in the treatment of the case. Suitable dressings must be employed to retain the foot in the corrected position until the slack has been taken up in the elongated tissues of the convex side, and until use has rendered supple the articular surfaces in their new relations. After operative procedures, plaster-of-Paris forms the most convenient dressing until the wounds have healed; after that the Taylor shoe is a simple, inexpensive, and satisfactory dressing.

Valgus.—Pure valgus is an exceedingly rare deformity. In congenital cases the outward deformity is almost in-

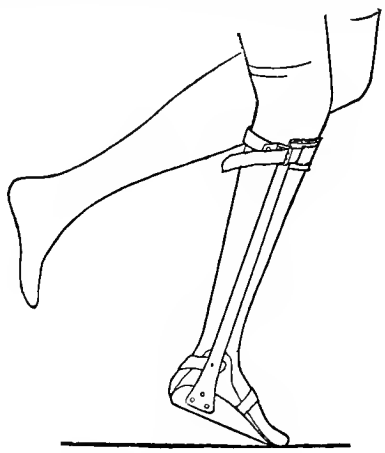

Fig. 94.—Judsons's brace applied.

variably associated with a dropping of the heel—calcaneo-valgus; in the non-congenital deformity the same condition may be present, or there may be drawing up of the heel—equino-valgus. In the congenital deformity the foot can, as a rule, be readily replaced by hand, and only requires a simple apparatus to retain it in that position. Occasionally, section of one or more tendons anteriorly is required. In equino-valgus, tenotomy of the tendo Achillis is indicated. Judson's brace, shown in Figs. 93 and 94, serves the best to retain the corrected foot in these outward deformities, as it also does in pure calcaneus. The brace consists of a sheet-steel foot-piece with a flange running its full length, turned up on the side to which the deformity looks, and on the opposite side a flange from one-half to one inch in width, turned up opposite the heel, to form the heel-cup. To the first flange is riveted an upright piece of soft bar-steel which runs along the side of the leg to the garter-line, where a band encircles the leg. The brace is held in position by straps so placed as to retain the foot in its new position.

Flat-Foot. The treatment of flat-foot, or acquired valgus, has been greatly advanced by the work of Dr. Royal Whitman, of New York. He divides the cases clinically into five groups:

1. Cases known as weak ankles in weak or rachitic children, or accompanying slight knock-knee.

2. The long weak foot seen in adolescence, which, though of little importance at the time, often becomes most confirmed and painful in later life.

3. Weak feet in older subjects, particularly women who have grown stout and are obliged to stand much of the time.

4. The most important cases, usually seen in young adults, where we find marked deformity and muscular

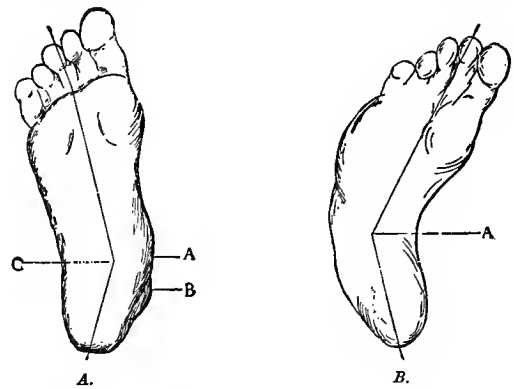

Fig. 95.—*A.* The flat-foot. *B.* The overcorrected foot.

spasm, so that the foot is quite rigid, and cannot be replaced in normal position.

5. True flat-foot, or pes planus, which may be actually inherited or be the result of rachitis in infancy.

The first and second class find relief in well-fitting shoes, the inner border of the soles of which have been built up from one-fourth to one-half inch, from the ball

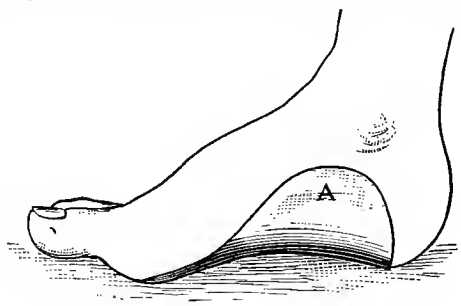

Fig. 96.

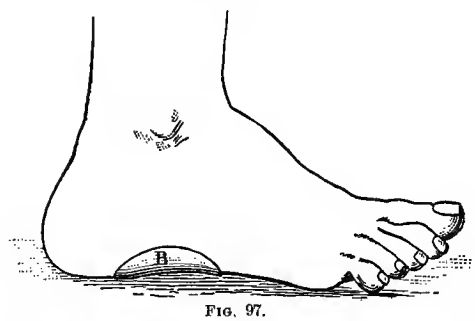

Fig. 97.

Figs. 96 and 97.—Whitman's flat-foot brace. A, the part applied to the inner side of the foot; B, that applied to the outer side.

of the foot to the tip of the heel, so that the weight is thrown to the outer side, and may be permanently cured by learning to walk properly, *i.e.*, with their toes in front so that the inner borders of the feet are parallel, and not with toes turned out.

To this treatment the third class should add hot foot-

baths, manipulations and rubbing, and in some cases Whitman's brace may advantageously replace the tilted shoe.

The fifth class requires no treatment unless pain is present.

It is to the fourth class that Whitman's principles of treatment are especially applicable, and the class in which his brace finds its greatest usefulness.

The procedure with it is as follows:

The deformity is forcibly reduced and overcorrected. This is quite a different thing from remoulding the arch (Fig. 95). Under ether, the foot is grasped by the hands, or the hands and knees, or by the Thomas wrench, and bent and twisted inward until all restriction to normal motion is completely overcome. The foot is then placed in extreme adduction or equino-varus, and retained by a well-padded plaster bandage. In a week, or less if there be no pain in the foot, the bandages are removed and a plaster cast taken for the support which is to be used. The plaster cast of the foot goes to the iron founder, who reproduces it in iron. Upon the iron cast is moulded, from thin sheet-steel while hot, the brace, in the form shown in the illustrations (Figs. 96, 97, 98) and afterwards it is tempered, nickeled, or tinned, and coated with Japan varnish. The brace is not a spring; it is inelastic. It is worn inside, but not attached to the shoe. The shoe recommended is one of the Waukenphast pattern, with a sole broad enough to support the foot, having an inward twist to allow room for the great toe. In advanced cases the inner side is built up after the method of Thomas.

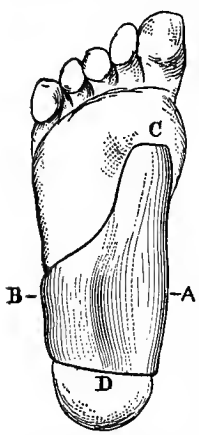

FIG. 98. — Whitman's brace, as seen from below, when applied to the foot.

Meantime the foot is manipulated daily to stretch the contracted and shortened tissues, until every part is free and supple. Voluntary exercises are also made use of to strengthen the weakened muscles. And lastly the patient is re-educated in the proper manner of walking and supporting weights (Fig. 99). The feet should be parallel as

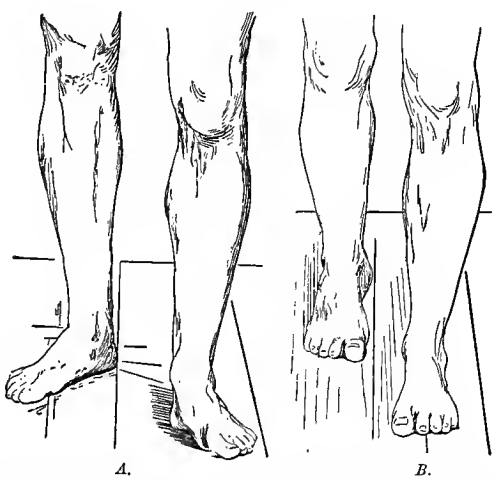

FIG. 99.—*A.* Improper position of the feet in walking. *B.* Proper position of the feet in walking. Each step is a gymnastic exercise.

to their inner borders, so that the weight will not be unduly thrown to the inner side of the foot, as is the case when the toes are far apart; and by walking over the toes instead of over the inner side of the foot, each step becomes a beneficial gymnastic exercise.

John Ridlon.

COCAINE. Since the appearance of this HANDBOOK cocaine has maintained its place as a local anæsthetic, and has gained for itself quite an extensive field of usefulness. It has been incorporated into the Pharmacopœia of all countries. Since attention has been directed toward the anæsthetic properties of cocaine quite a number of other bodies have become known that have local anæsthetizing effects, as for instance, erythrophleine, menthol, and other compounds, part of which belong to the groups of glycocides or resins. All these bodies have that in common, that they act as intense irritants upon the terminations of the sensitive nerves, and that after a longer or shorter period of irritation a period of paralysis (anæsthesia) follows, which is the case also with cocaine. In most of these drugs the primary irritation is very much stronger than in cocaine, a circumstance which did not permit their substitution for it. Some of the alleged rivals of cocaine have been disclosed as downright deceptions, as for instance stenocarpine (mixture of cocaine and atropine). With the increased knowledge regarding the chemical constitution of cocaine (see under that heading), the time does not seem distant when cocaine, or some body of similar constitution and physiological action, will be synthetically manufactured for practical use, as in fact has been done already in the laboratory.

MODE OF MANUFACTURE AND STATISTICS.—Great progress has been made in the manufacture of cocaine, which has led to a remarkable reduction of its cost, the market price at present (end of 1892) being $6 the ounce. The table below (for which the writer is indebted to the courtesy of Messrs. McKesson & Robbins) shows the following decrease in price:

Autumn of 1884 (abnormally high price)	$3.00	per grain.
End of 1884	.50	"
1885	.30	"
End of 1885	.05	"
1886	.05	"
1887	7.50	per ounce.
1888	7.00	"
1889	6.00	"
1890	5.50	"
1891	8.00	"
1892	8.00	"
End of 1892	6.00	"

The former process was essentially the one used by Niemann, only somewhat modified. The alkaloid was extracted from the leaves by means of acidulated alcohol, much ether being used in the further steps of the process, as described in Vol. II., p. 217, of this HANDBOOK. The main improvement consists in dispensing entirely with the alcohol and using ether in very moderate quantity only. Cocaine, like other alkaloids, is soluble in kerosene oil, while its salts are not soluble in it. If ground leaves are moistened with a five per cent. solution of sulphuric acid, percolated, and the percolate is agitated with kerosene and an excess of carbonate of sodium, the alkaloid is held in solution by the kerosene, comparatively free from other matter. It can be washed out of the kerosene by means of acidulated water. For purposes of purifying it is precipitated again by carbonate of sodium, then dissolved in ether, from which it is washed out by dilute hydrochloric acid as the hydrochlorate salt. This process has also been improved upon by doing away with the extraction from the leaves by means of acidulated water. The ground coca leaves are moistened with a solution of carbonate of sodium, and the alkaloid directly extracted from them by percolating with kerosene. From this kerosene solution the alkaloid is washed out by means of weak sulphuric acid, and for purposes of purifying precipitated again by carbonate of sodium in the presence of a small portion of kerosene to dissolve it again. This process of precipitating and redissolving is repeated several times. At last the crystals of the crude alkaloid are dissolved in dilute acid and freed from kerosene by means of ether; then the alkaloid is precipitated again in the presence of ether, the clear ethereal solution (of the alkaloid hydrate) shaken out with hydrochloric acid, and the solution of the hy-

drochlorate evaporated to dryness.* At first all cocaine made was extracted from the leaves in Europe and in this country. The coca-leaves have to be transported a long way from the mountain range of Peru and Bolivia, on the backs of mules, and farther by railway to the Chilean and Peruvian ports. The combined influences of heat and moisture to which the leaves were exposed during this transportation robbed them of part of the amount of the alkaloid they originally contained. This circumstance, and the considerable expense of transportation of the dead weight, have caused the manufacture of cocaine to be transferred to the source of supply in the Bolivian Mountains, where various manufactories have been established to turn out the crude alkaloid. This is exported to Europe and to this country in cakes of several inches in diameter and half an inch in thickness. It is then refined and converted into the hydrochlorate by the process described above. The present import duty, discriminating against the crude alkaloid (twenty-five per cent. ad valorem against fifty cents a pound on the salt), has hampered American manufacturers, so that almost all cocaine here consumed is imported from Germany, where it is manufactured partly from leaves, partly from the crude alkaloid. A small quantity is made here from leaves, of which 90,000 pounds are imported per annum. Cocaine salts are used in the United States to the amount of 100,000 ounces (3,125 kilogrammes) a year (estimate of Messrs. McKesson & Robbins; Dr. Squibb puts the figure at 1,800 kilogrammes, giving this as a crude computation based on the output of his own factory).

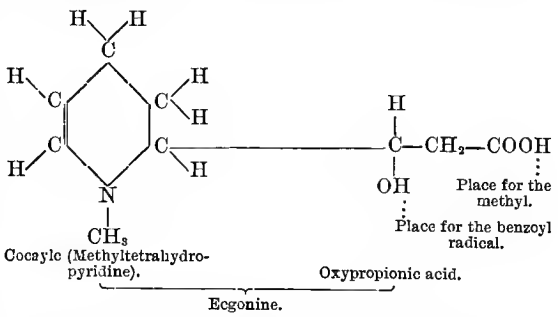
The annual harvest of coca-leaves in South America is estimated to be 10,000,000 kilogrammes, of which about five per cent. is exported, either in the natural condition or in that of the crude alkaloid, extracted in the Peruvian manufactories. The variety best suited for the extraction of cocaine is the great-leaved species cultivated in Southern Peru (Huanuco, Huanta, Santa Anna), containing about 0.5 per cent. of the alkaloid. Bolivia furnishes not very considerable quantities of coca, as the price is fifty to eighty per cent. higher than for the Peruvian. The so-called Trujillo coca, from Northern Peru, is not well suited for the manufacture of cocaine, as it contains hardly half as much of this alkaloid as the Southern plant, but great quantities of other alkaloids, which make the isolation of cocaine very difficult.

Experiments to raise coca elsewhere have been made in the Government of Madras, in the tea-plantations of Bengal, in the Island of Ceylon, on Mount Café, at San Thomé in Africa, and in the cinchona plantations of Java. The latter ones gave the best results, and the coca exported from Java is very similar to Trujillo coca (Northern Peru) in aspect and in the amount of alkaloid contained. It contains 0.2 per cent. cocaine, besides a quantity of other alkaloids that hamper manufacturing. (Information furnished by the firm of C. F. Boehringer u. Söhne, Mannheim, Germany.)

Tests of Purity.—*Maclagan's test* consists in dissolving one grain hydrochlorate of cocaine in two ounces distilled water and adding one to two drops of ammonia solution. If free from amorphous cocaine, on stirring the ammoniated solution a few seconds cocaine hydrate separates out in crystalline form and falls to the bottom, leaving the supernatant solution clear and free from opalescence. If at all milky, the presence of amorphous cocaine is indicated. (Copied from *The* [London] *Chemist and Druggist*, March 5, 1887, p. 297.)

Permanganate Test (Garthier).—When a solution of two centigrammes to half a gramme of hydrochlorate of cocaine is mixed with one drop of a two per cent. solution of permanganate of potash, the resulting fluid must assume a red color and remain transparent. On a subsequent addition, drop by drop, of the permanganate solution, there must appear a red precipitate consisting of permanganate of cocaine, which becomes brown only after heating and that without evolving an odor of bitter almonds. When the addition of one drop of the permanganate solution brings about a brown discoloration or brown precipitate, or when on heating the mixture there appears an odor of bitter almonds, the preparation is impure and unfit for use. (Copied from the London *Med. Record*, 1889.)

Chemical Constitution.—Cocaine, if heated with hydrochloric acid splits into benzoic acid, methyl alcohol, and a new alkaloid, ecgonine ($C_9H_{15}NO_3$), of not well pronounced physiological action. Recent investigations have shed light on the manner in which these parts are arranged in the cocaine molecule and on the constitution of ecgonine (Einhorn, *Berichte der chem. Gesellschaft*, xxi., p. 3029, 3441, vol. xxii.; Stoehr, *ibid.*). As was to be expected, there is an intimate connection between the constitution of the cocaine molecule and its physiological action. There exist quite a series of bodies similarly constituted, with analogous physiological action, facts that have been studied by Ehrlich (*Deutsche med. Wochenschr.*, 1891, No. 32, p. 717) and E. Poulsson ("Beiträge zur Kenntniss der pharmakologischen Gruppe des Cocain," *Arch. f. experimentelle Pathologie u. Pharmakologie*, vol. xxvii., p. 301). In ecgonine a group called Cocayle, $(CH_3)NC_5H_7$, whose constitution is methyltetrahydropyridine, is combined with the radical of oxypropionic acid, thus:



The side chain in this molecule (oxypropionic acid) contains a hydroxyl and a carboxyl, with either of which different radicals can unite.

Whenever an alcohol radical is affixed to the carboxyl group, and at the same time an acid radical enters the other replaceable hydroxyl group, the resulting body in chemical and physiological action closely resembles cocaine. In this latter methyl (CH_3) and benzoyl ($C_6H_5CO_2$) are the two radicals entering into the oxypropionic rest. The coca-leaves contain various cocaines with radicals other than those given above, and by chemical synthesis a great number of them have been formed. So the methyl of the ordinary cocaine has been replaced by ethyl, giving rise to coca-ethyl and the benzoyl has been substituted by the radicals of baldrian-, cinnamon-, or phenyl-acetic acid, thus leading to another series of homologous alkaloids. But this does not exhaust the possibilities for the formation of bodies similarly constituted and with similar physiological action. The radical of the oxypropionic acid contained in the ecgonine molecule can be replaced by other acid radicals, which of course must contain one carboxyl and one hydroxyl group. In fact, by oxidizing ecgonin, Einhorn has succeeded in composing a body which contains oxyacetic acid instead of oxypropionic acid. By introducing the benzoyl and the ethyl in this new combination a body is obtained which is isomeric with cocaine and possesses highly anæsthetic qualities, at the same time surpassing cocaine in poisonous effects, as Ehrlich has found. Experiments with a number of these cocaines and their components have shown that the alcohol radical above mentioned is essential for the anæsthetic effect, and that with its removal from the cocaine molecule the anæsthetizing and poisonous properties disappear (Poulsson, *loco citato*).

* For the information regarding the actual process of manufacture I am indebted to Dr. E. R. Squibb's personal communication; it is drawn partly also from his journal Ephemeris. The process above described applies only to his factory, but most likely a similar one is employed in other establishments.

ELEMENTARY ACTION OF COCAINE.—Our knowledge of the manner in which cocaine acts as a local anæsthetic has been materially promoted by a number of investigations on its action on various living cells and tissues. That the local anæmia observed upon local application cannot be the cause of the anæsthesia, as several authors have asserted, must be apparent to everybody, who applying it to the eye notices that the anæsthesia of the cornea precedes the anæmia of the conjunctiva. Several facts, as for instance the slight cloudiness and the dotted erosions of the corneal epithelium after repeated applications of cocaine, pointed to this drug being a general protoplasma poison, first stimulating and then mortifying it. The writer, who in his first experiments noticed the haziness of the corneal epithelium, was inclined to consider it due to evaporation, in consequence of the arrested secretion of tears and diminished winking of the lids, brought on by the local anæsthesia. When, with the increasing general use of cocaine as an anæsthetic, reports began to come in about opacities of the cornea occurring after operations in which cocaine and simultaneously solutions of corrosive sublimate had been used (Herschel, Bunge), the writer set out to determine this question by experiment. Wuerdinger, of Munich ("Experimentelle und anatomische Untersuchungen über die Wirkung des Cocain auf die Cornea," *Klinische Monatshefte für Augenheilkunde*, 1886), had come by his experiments and his pathological researches to the conclusion that the haze was due to dryness of the cornea. In 1886, while in Utrecht, the writer conducted a series of experiments on rabbits, the results of which, however, were never published. Cocaine was instilled into the rabbit's eye and the lids carefully closed over it with an artery forceps, while the other eye was kept open by means of an eye speculum. The eye that had been kept open (and into which no cocaine had been instilled) showed drying and loss of epithelium after several minutes, while the cocainized eye showed that by carefully protecting it, the hazy appearance and loss of epithelium in it had been reduced to a minimum. Evidently, therefore, evaporation was a factor to be taken into account. [Other experiments established the evidence that the corneal epithelium is especially prone, when cocainized, to become hazy by washing the eye with solutions of corrosive sublimate (of the concentration as used in eye surgery, 1 to 4,000–5,000).] But however careful or however often the experiment was made, repeated instillations of cocaine would always produce some haziness and some dotted defects of the epithelium—a condition, though, that would return to the normal within a few hours. It was nearly certain, therefore, that cocaine, as such, affects epithelial cells in their vitality. This probability became stronger yet by comparison with the action of erythrophleine, an alkaloid extracted from the bark of *erythrophlœum guineense*. This alkaloid, like a number of others, has very strong anæsthetic properties, even stronger than cocaine. The irritation preceding the anæsthesia is much more marked and of longer duration than in the case of cocaine, and correspondingly the inroad upon the vitality of epithelium and corneal tissue is a more vehement one. Two drops of a one-eighth per cent. solution instilled into the writer's eye (Koller, *Wiener medicinische Wochenschrift*, 1888, No. 6, and *Chicago Medical Journal and Examiner*, April of the same year) proved to be sufficient to set up an irritation of thirty-five to forty minutes' duration and to produce a distinctly visible opacity of the cornea, which took two days to disappear entirely. (This property, together with the highly poisonous action of the drug, has prevented the practical use of it recommended by Lewin.*) The initial irritation, the ensuing anæsthesia, and the simultaneous clouding of the epithelium are all proportionate in the action of the two drugs and strongly point toward an intimate, or rather a causal, connection.

Extensive researches on the action of cocaine upon the vital manifestations of various kinds of cell-elements and low animals instituted by Albertoni (Pietro Albertoni, "Azione della cocaina sulla contractilita del Protoplasma," *Ann. d. Chim.*, 1890, p. 305) have shown that cocaine is a protoplasma poison. According to its concentration and the duration of its action it stimulates or paralyzes the protoplasma in its vital functions. For instance a 0.25 per cent. solution applied to the palate of a frog stimulates the activity of the ciliated epithelium, so that particles of coal-dust are moved along with four times the ordinary velocity, while two per cent. solutions slacken the velocity to the fourth or sixth part of the normal. Grubs of butterflies and amœbæ in a physiological solution of ClNa stop their movements upon the addition of one-half to two per cent. cocaine, and so do the large white blood-cells of astacus. Spermatozoids and other ciliated cells stop their movements in strong solutions of cocaine or when subjected to the protracted action of weaker ones. The mucous glands in the membrana nictitans of frogs lose their ability to respond to electrical stimulation. The effects of the electrical current observed in pieces of muscle and nerve disappear soon under the influence of cocaine. So the experiments of Albertoni have established beyond a doubt the view, which was the most reasonable and probable one, that the local anæsthesia is the effect of a paralyzing influence upon the ends of the sensitive nerves. A pathological supplement to this theory is the fact that nerve-fibres in five per cent. solution of cocaine look less bright than they do in 0.6 per cent. ClNa solution (Alms, "Wirkung des Cocain auf die peripheren Nerven," Du Bois Reymond's *Archiv für Physiologie*, 1886). A peculiarly characteristic and deleterious effect is exercised by cocaine upon the cells of the liver. The livers of mice, which Ehrlich ("Studien in der Cocainreihe," *Deutsche Med. Wochenschr.*, No. 32, p. 717) had fed with cocaine (0.01 to 0.02 to the "cake," Prince Albert cracker), and which had perished within a few days under this diet showed considerable increase in volume, and their macroscopic appearance reminded one of the stuffed-goose liver. The microscopical examination showed vacuolar degeneration of the cells; the latter were enlarged, contained many vacuoles, and very small remains of protoplasma about the nucleus. No glycogen was to be found in the cells, nor in fact in the whole liver. The hepatic connective-tissue showed fatty degeneration and "coagulations-nekrose;" the stellated cells and the endothelia of the blood-vessels showed also fatty degeneration.

ACTION UPON NERVE-TISSUE.—The action of cocaine upon nerve-tissue, therefore, cannot be considered as being of a specific kind, but is rather identical with the general action of this drug upon protoplasma, the only difference being that the nerve-tissue responds more readily and more effectively to outside influences. In accordance with this view one would expect that all nerve-tissue would be similarly affected by it, although the action upon the ends of the sensitive nerves is most marked and constitutes the most striking property of cocaine and its main claim as a valuable therapeutic agent.

In order to test the action of cocaine on other than peripheral sensory nerves, the writer devised a series of experiments, with the purpose of deciding the question whether the terminal apparatus of the higher senses could also be paralyzed by cocaine. The field of experiment selected was the retina. In two cases in which an enucleation of the eyeball had to be performed, perception and projection of light being still present, cocaine was injected into the orbita by means of a hypodermic syringe, as near to the eyeball as possible. In one of these cases it was apparent that the perception of light was affected in that part of the field of vision which corresponded to the place of injection. Continued injection in other places around the eyeball blinded other corresponding parts of the field, until after some time nearly all perception of light was lost. The other case did not give any satisfactory result, on account of which these experiments were not published. (The experiments were made in Professor Snellen's Eye Clinic, in Utrecht, in 1887). Experiments on dogs, undertaken in common with Dr. H. Zwaardemaker, in Utrecht, failed, on account of the toxic effect of the doses necessary. Later on, Dr. H.

* Paper read before the Berlin Med. Soc., January 11, 1888.

Zwaardemaker ("Cocain-Anosmie, Fortschritte der Medicin 1. Juli, 1889") tested the action of cocaine on the sense of smell, and by means of the olfactometer, examamined the way in which the smell was affected when cocaine powder of five, ten, and twenty per cent., was blown up the nose. He found that if sufficiently absorbed by the mucous membrane of the upper parts of the nose, it produces anosmia, preceded by hyperæsthesia of smell. The various qualities of smell were equally affected.

Tumass ("Über die Wirkung des salzsauern Cocains auf die Psychomotorischen Centren." *Arch. f. Exper. Path. ü. Pharmakol.*, 1886–7, xxii., 107–126) has shown that cocaine has the same paralyzing influence upon the gray matter of the cerebral cortex. He experimented on dogs, applying from 0.05 per cent. to 4 per cent. solutions to the psychomotor centres of the cortex, which had been laid bare by trephining. The result was that, after cocaine application, stronger currents were necessary to produce just noticeable contraction of the corresponding muscles. The reduction of irritability lasted fifteen minutes, whereupon it slowly increased, but did not reach the normal within forty-five minutes. The trunks of thick sensory nerves were affected in the same way when moistened with a solution of cocaine; they could be cut without the slightest manifestation of pain. Other observers obtained the same results. The experiments of Goldscheider ("Wirkung des Cocain, etc., auf die Sinnesnerven der Haut.," *Wochenschr f. prakt. Dermatologie*, 1886, 2), Kochs ("Wirkung des Cocain auf Freipraeparirte Nerven.," *Centralblatt f. Klin. Med.*, 1886, No. 33), and Alms ("Wirkung des Cocain auf die peripheren Nerven.," *Du Bois Reymond's Arch. f. Physiologie*, 1886), show that the application of cocaine to the trunk of a sensory nerve produces peripheral anæsthesia, so that the cocainized part of the nerve seems to constitute an impediment for conduction. The same experience can frequently be made, when cocaine is applied subcutaneously for surgical purposes, and the place of application is near a sensory nerve-trunk. The action of cocaine upon motor nerve-trunks is essentially the same, although the conditions are here so complicated as to make that fact less evident than in the case of sensory nerves.

If a cocaine solution is applied to the trunk of a mixed nerve of a frog, the limb controlled by that nerve seems paralyzed both in its sensory and motor functions; but upon further examination it is found that the motor paralysis is only a consequence of the muscular and cutaneous anæsthesia (Vulpian "Comptes Rendus," xcix., p. 887, and Alms, l. c.), for reflex-action can be produced by irritation of other points of the body in the apparently paralyzed muscles. Nevertheless, irritation above the cocainized point (experiments made by Alms, on rabbits) discloses a marked decrease in irritability, so that cocaine acts on motor the same way as on sensory nerves; that is to say, it impedes the conduction of a stimulus. The paralyzing action on the terminal apparatus of the motor nerves has been demonstrated by Alms. If cocaine is injected into the arteria iliaca communis of one side in a frog, precautions being taken at the same time to prevent the cocaine from passing into the general circulation, the muscles of the leg of that side become completely paralyzed; faradic stimulation of the sciatic does not cause contraction, while the muscles retain their direct irritability. Cocaine applied in this way has exactly the same effect as curare has when introduced into the blood-circulation.

The Action of Cocaine upon the Organism depends of course upon this nerve-stimulating and paralyzing property. A number of more recent investigations of the physiological action of cocaine have brought to light new facts of great importance. To be complete, the following summing up may be in place:

The *central nervous system* of all animals is paralyzed by cocaine in sufficient doses after a period of excitation, which latter in warm blooded animals is characterized by general convulsions, while in cold blooded animals they are absent. The convulsions are of a general character and of the type of tetanus, and opisthotonus; they are certainly of central origin (not reflex-convulsions, as they occur at a time when the animals no longer react under the strongest stimulants) and their seat is most likely the medulla oblongata (Anrep, Tumass). The animals die most frequently during these convulsions by suffocation due to tetanus of the respiratory muscles—incidentally as it were, for, if they survive the convulsions, finally paralysis of the entire nervous system sets in, sensibility is lost, reflexes disappear, respiration ceases, the heart stops beating. After very large doses of cocaine this paralysis is developed directly without the intervention of convulsions. [According to the statements of Mosso *Arch. f. Experim. Pathologie u. Pharmakologie*, xxiii., 3-4, 1887), 0.005 per kilogram will sometimes produce general symptoms of poisoning, while he puts the fatal dose at 0.03 per kilogram. The fatal dose for men is about half that amount.] Small doses, 0.03—0.05—0.1, produce a decided enhancement of the psychical functions, euphoria, and increased capacity for mental and physical work, as shown by the experiments of Freud ("Beitrag zur Kenntniss der Cocawirkung." *Wiener medic. Wochenschr.*, 1885, No. 5), and many other observers with whom the writer, from his own observations, fully agrees. This effect is most likely due to stimulation of the gray cortical matter. The powerful effect large (but not toxic) doses have in altering the psychical functions (hallucinations, deliria, irresistible impulse to move) is too well known, from Anrep's dramatic description of his experiments on dogs, to be repeated. It will be partly described under the heading, Accidental Poisoning. The exciting effect of large doses is not confined to the cortex. It includes the great subcortical ganglia, the cerebellum, the medulla oblongata, and the spinal cord, as is evident from the forced movements, the vertigo, the convulsions, and the circulatory and respiratory phenomena.

Eye.—The action of cocaine, introduced into the general circulation, upon this organ is very similar to its action when applied locally; the pupil is dilated, the eyeball protudes, the eye is opened wider,—symptoms due to irritation of the sympathetic nerve. We must look for the seat of its action upon the sympathetic nerve (when introduced into the general circulation) in the nuclei of the sympathetic in the cord and medulla, for if the sympathetics is severed in dogs after 0.1 cocaine has been injected into the vena saphena, the above symptoms do not appear on the corresponding side ("G. N. Durdufi, zur physiologischen Wirkung des Cocain." *Deutsche med. Wochenschr.*, 1887, xiii., 172-174). The dilatation of the pupil after general, just as after local application, must be ascribed to the contraction of the iris-arteries, as there does not exist another dilater of the pupil in the human eye.

Respiration.—Cocaine always accelerates the respiration by stimulating the respiratory centrum. Large doses produce very frequent dyspnoic breathing, increasing to tetanus of the respiratory muscles. Fatal doses finally paralyze respiration.

Circulation.—In small and medium doses cocaine increases the frequency of the heart-beat, small doses rendering the contraction at the same time more powerful (Mosso). The increased frequency is most likely due to stimulation of the accelerating nerves of the heart (Durdufi). Large doses finally paralyze the heart (the action is different in frogs, the frequency being diminished instead of being decreased).

Very peculiar and characteristic is the action of cocaine upon the blood-vessels. Local application has a powerful constringent effect upon the small blood-vessels, making the tissue affected almost anæmic, as we can observe every day when applying cocaine to the nose or to the eye. This action upon the blood-vessels is evidently due to a stimulating effect of cocaine upon the nerves of the smooth muscular fibres. The contraction resulting is of long duration (several hours) and is followed by a relaxation. [Again here we find a difference in frogs. Local application of even weak solutions (1 : 4000) to the frog's tongue, produces considerable dilatation of the blood-vessels.] Introduced into the circulation, cocaine has the same constricting action upon the blood-vessels, and this evidently by means of acting upon the cen-

tres of the nerves of blood-vessels, as, for instance, is shown by the dilatation of the pupil (anæmia of the iris) not appearing if the sympathetic nerve has been severed. The pressure in the arteries is increased by medium doses in consequence of constriction of the small blood-vessels. Fatal doses lower the pressure accordingly.

The secretion of urine is materially increased by medium doses (even to the double of the normal) just on account of the increase of pressure in the arteries; very large doses diminish and finally stop urine secretion (Bignon: "Des Proprietés toxiques de la Cocaine," *Bullet. gén. de Thérap*, 1886, ii.).

Intestines.—Peristatic movements are increased; very large doses paralyze the intestines, which at the same time become very hyperæmic.

Secretion of saliva and perspiration stops after local application, and also when the drug acts by way of the circulation, most likely on account of the paralysis of the secreting epithelium, and constriction of the blood-vessels.

Practical Use.—*Eye Surgery.*—Cocaine is used for a threefold purpose: As an anodyne in painful affections; as a local anæsthetic in eye operations; as a dilater of the pupil.

Owing to the short duration of the cocaine anæsthesia (about fifteen to twenty minutes), its use as an anodyne is a limited one. Naturally it would be most useful in pains caused by superficial erosions, or ulcers of the cornea. The weakening effect upon the vitality of cells (as shown in the paragraphs devoted to the consideration of its action on cell elements) does not make a frequently repeated and prolonged action desirable. It is found very useful in the examination of an eye, where pain, photophobia, and lachrymation would otherwise render such an examination almost impossible, as in conjunctival or corneal troubles, cases of superficially seated foreign bodies, scalding by chemicals, etc. In pains which might possibly be of glaucomatous origin the use of cocaine should be carefully avoided, as it has repeatedly been found to hasten the development of a glaucomatous attack previously threatened (Javal). Supra- or infra-orbital neuralgia can frequently be successfully combated by hypodermic injection. The use of cocaine as a local anæsthetic in eye operations is a very extended one, and it has reduced the employment of general anæsthesia by ether or chloroform to a minimum. The objections raised against it in the beginning, of producing sometimes opacities of the cornea after cataract operations, have been silenced by its more judicious application, by prevention of evaporation, and by avoidance of the too free use of sublimate or other coagulating antiseptics. Another objection raised by several writers, that the cocaine anæsthesia renders the eye so hypotonic that the expression in operation for cataract becomes difficult, has not been heard of in the more recent literature. On the contrary, many operators who follow the trend of the time by practising cataract extraction without iridectomy, consider the revival of this more perfect method as partly due to the cocaine anæsthesia, the latter being instrumental in preventing prolapse of the iris. While operations on the conjunctiva and on the cornea can always be made perfectly painless by *instillation* of cocaine solutions, such operations in which the iris is touched or cut, as iridectomies and operations for cataract, cannot always be rendered perfectly painless by instillation, owing to the difficulty of making the iris sufficiently anæsthetic. In a number of cases one does succeed, in another number one does not. The writer has found the following to be the most effective method of instillation: Begin to instil a four per cent. solution, twenty to thirty minutes before the operation (time necessary to reach the iris), instilling at intervals of five minutes each. During the whole time the eye is kept closed to prevent evaporation. The iris can, with certainty, be rendered anæsthetic by instilling cocaine into the anterior chamber after the corneal section. A Daviel's spoon is inserted through the corneal wound into the anterior chamber and a drop of cocaine allowed to run into it along the furrow of the instrument; the spoon is withdrawn, the speculum removed, and the eye closed for two to three minutes. Although this proceeding complicates the operation it has its justification in the great importance of complete anæsthesia of the iris for the safety of the operation. If prolapse of the iris occurs right after the corneal section some of the advantage of this procedure is lost. In a proposed iridectomy it is therefore best not to allow the whole of the aqueous humor to escape during the corneal section. For operations on the tendons and muscles (tenotomies and advancements) instillation is never sufficient for a complete anæsthesia, and therefore, as far back as 1885, the writer resorted to subconjunctival injections in these operations. He proceeds as follows: After repeated instillation of a four per cent. solution, to make the conjunctiva anæsthetic, a speculum is inserted, and, by means of a mouse-toothed forceps, a fold of the conjunctiva at the point of operation is seized. The needle of a hypodermic syringe is inserted into it, if possible, as deeply as Tenon's capsule and a few drops of a two per cent. solution are injected. Then the eye is closed again after removal of the speculum, and the artificial œdema of the conjunctiva is given time to disappear, which it does in five to ten minutes, aided by occasional slight rubbing. In this way the operation can be performed absolutely without pain. The cocaine solution is made aseptic by filtering and boiling, which latter does not affect its efficiency. The syringe is cleaned with alcohol and rinsed with a two per cent. carbolic or three per cent. boracic solution or sterilized water. Recently the writer has used these subconjunctival injections very successfully in cataract operations and in iridectomies, following a suggestion made to him by Professor Snellen, of Utrecht, in a private communication (see also Snellen, "Sur l'Opération de la Cataracte," *Annales d'Oculistique*, Janvier, 1892). The proceeding is the same as that described for squint operations, the point of injection to be selected near the place of intended corneal section.

The *pupil-dilating* property of cocaine is of great value in ophthalmoscopy. While the dilatation is sufficient in the dark chamber to allow a satisfactory examination, it does not have the blinding effect of belladonna, the pupil all the time responding to light. This is due to the fact that cocaine dilates the pupil by constricting the blood-vessels of the iris, but leaves the sphincter intact. Besides, the accommodation is hardly interfered with. The pupil-dilating power of cocaine, if combined with that of atropine, is invaluable in cases of iritis. The mydriatic effect of this combination is stronger than that of any other drug or any combination of drugs; it counteracts both forces that contract the pupil—the sphincter and the blood-vessels. (Hyperæmia of the iris tends to contract the pupil by stretching the tortuous course of the iris arteries, while the blood-vessels, when empty, return to their tortuous course and so dilate the pupil.)

The anæmia of the blood-vessels is a strong check to the inflammation, the pain ceasing mostly after a few instillations, and the duration of treatment being greatly shortened. The writer uses a mixture of equal parts of a one per cent. solution of sulphate of atropine and a five per cent. solution of hydrochlorate of cocaine; at first he instils every ten minutes until the pupil is dilated (three to four instillations necessary), then only three times a day. The combination of the two drugs is also efficient in cases of cyclitis.

Rhinology and Laryngology.—In the examination and treatment of the nasal cavities cocaine has an extensive field of usefulness. By its power of constricting the blood-vessels the mucous membrane recedes and inspection of the posterior parts is facilitated; in chronic catarrh with hypertrophy a proper inspection without its help would be impossible. Medicated applications and the actual cautery or caustics can be employed painlessly. In reflex neuroses starting from the nose the exact locality of the trouble can be detected, inasmuch as by application of cocaine to the starting-point the patient is temporarily relieved (asthma, mimic spasm, etc.). In hay fever it affords relief but has no curative power. Posterior rhinoscopy is facilitated by checking the reflex

action of the soft palate and the tedious practising of the patient is done away with. The solutions are applied either as a spray by means of an atomizer or with a cotton wad on the point of a probe. For spraying, only weak solutions (two per cent.) should be used, in graduated bottles, so that the quantity used is known, to avoid the possibility of poisoning. Weak solutions applied repeatedly at intervals of five minutes will accomplish the same result as strong ones; the first application constricts the blood-vessels and the following ones act more strongly on the anæmic membrane, while at the same time a too rapid absorption, with its poisonous effects, is prevented. For application with brush or cotton stronger solutions (five, ten, or fifteen per cent.) may be used. Nasal surgery has been greatly promoted by the use of cocaine. Operations on the septum and the turbinated bones can frequently be performed painlessly, although not always so. Laryngological examination and operation is made easier by stopping reflex action of pharynx and larynx; the practising of the patient is done away with. For making the vocal cords anæsthetic very strong solutions (twenty per cent.) are required; they are applied with brush or cotton.

Otology.—Comparatively little advantage has been brought to otology by the use of cocaine. The drum-head (covered with epidermis) can hardly be rendered completely anæsthetic, but the sensibility can be lessened by repeated application of a warmed fifteen to twenty per cent. solution (Hedinger). In operations in the tympanic cavity more can be expected from its anæsthetic effects, although, only if the operation is limited to the mucous membrane (Kretschmann: "Communication about the Experiences made in Schwartze's Clinic," *Arch. f. Ohrenheilk.*, xxiii., 4, 1886). Catheterization of the Eustachian tube is facilitated and made painless; the air penetrates in broader current into the tympanic cavity. Hedinger (*Würtemberg. Corr. Blatt.*, lvii., 7, 1887) relates favorable results in cases of inflammation of the middle ear. A few drops of a two to four per cent. solution blown into the Eustachian tube by means of a catheter were in most cases sufficient to stop the pain for several hours. Kiesselbach (*Monatsschrift f. Ohrenheilkunde*, xxiii., 9, 1889) had good success from insufflation of a few drops of a four per cent. solution into the Eustachian tube in cases of subjective ear-noises. The insufflations were made at intervals of three to five days, the strength of the solution being increased to ten per cent. The most various noises disappeared entirely; most cases improved.

General Surgery.—The use of cocaine in general surgery is very extended, and in minor operations has displaced general anæsthetics and other methods of local anæsthesia. It is injected under the skin or into the deeper layers of the skin at the site of the operation by means of the hypodermic syringe. Careful distribution over the field of operation is necessary for full effect. Corning's method of "incarceration" is an important improvement on the simple injection (J. Leonard Corning: "On the Prolongation of the Anæsthetic Effects of the Hydrochlorate of Cocaine when subcutaneously injected —an Experimental Study," *New York Medical Journal*, September 19, 1885, and "Local Anæsthesia in General Medicine and Surgery," in book form, Appleton & Co., 1886). A short time is given to the circulation to distribute the drug over the field of operation, then exsanguination of the limb and application of a tourniquet (especially devised apparatus on other parts) keep the solution in place. By this way of proceeding, the anæsthetic effect can be prolonged indefinitely, while absorption into the general circulation and poisonous effects are prevented.

At present extirpation of small tumors, extraction of foreign bodies, amputations of fingers and toes, operation for phimosis, operations for ingrown nail, incision of abscesses and furuncles, are performed under cocaine anæsthesia. Pernice (*Deutsche Med. Wochenschrift*, 1890, 14) reports more than a thousand cases operated in the Polyclinic at Halle, where one per cent. solutions were used, which were always found sufficient. One to two syringes were injected (0.01–0.02), and thus accidents could with certainty be avoided.

In genito-urinary surgery cocaine is extensively used, not only for external and internal urethrotomy, but also for operations in the bladder (litholapaxy). As the unbroken epithelium of the bladder has hardly any power of absorbing, enormous quantities have sometimes been used (1.00–5.00!!). However, genito-urinary surgery is especially rich in accidental poisoning, the assumption of an unabraded epithelium not always being correct.

Dentistry.—To make extraction of teeth painless it is not sufficient to brush the solution on the gums, as this does not make the alveolus anæsthetic. Even injection between gum and alveolus in one place only will frequently fail. All those who report successful anæsthesia (George Viau: "De l'Anesthésie buccale," Paris, 1886; Bleichsteiner, Congress of Dentistry, Paris) concur in the recommendation to inject the solution under the gum in several places on the inside and outside of the alveolus. A five per cent. solution is sufficient, and not more than 0.05 cocaine should be used. Even then the number of cases where constitutional symptoms occur is large compared with its application in other branches of surgery. Schlenker ("Ueber Cocain als locales Anæstheticum," *Tageblatt der* 61. *Vers. deutscher Naturf. und Aerzte*, Cöln, 1889) had three per cent. of graver and five per cent. of minor cases of poisoning. Bleichsteiner had collapse in five to six per cent. of his cases.

Gynecology.—Apart from the use in minor operations on the vulva, vagina, and the cervix, cocaine is especially valuable in the treatment of vomiting in pregnancy, vaginismus, and sore nipples. In cases of vomiting in pregnancy it has been found successful where all other medication failed, whether administered by the stomach, hypodermically, or by application to the os or cervical canal (Weiss: *Prager Med. Wochenschr.*, 1884, No. 51—0.004 internally every half-hour; Phillips: London *Lancet*, November 26, 1887). It is scarcely used any more at present in obstetrics; in the first enthusiasm it was recommended to alleviate pain in labor.

Dermatology.—Cocaine does not have any effect if applied to the unbroken epithelium. If the latter is macerated or wanting, solutions or ointments can be used to combat itching as in vesicular eczema, especially in the itching eczema of the genitals, in painful ulcers, and after cauterizing. In different operations on the skin, and before cauterizing, the application is the same as described under the heading of General Surgery. Touton reports painless treatment by electrolysis of warts or moles, if a few drops of a five per cent. solution are injected under the little tumor (which fact the writer can confirm). It is of theoretical interest that cocaine, like other substances, can be driven into the skin by the electrical current if applied to the positive pole—cataphoretic action of the galvanic current. (Wagner: "Ueber eine neue Methode Haut Anaesthesie durch Cocain zu erzeugen," *Zeitschr. für Therapie*, 1886, No. 6). The anæsthesia thus engendered may be used for superficial operations.

In *general medicine* much has been expected from the stimulating powers of cocaine upon the physical functions. However, it does not seem to be extensively used for this purpose, perhaps from exaggerated fear of the cocaine habit. From the experiments of Freud, Hammond, and others it is apparent that it has a decidedly stimulating power upon the psychical faculties, and some writers report very good results in neurasthenic patients and in melancholic depression (0.02–0.03 internally several times a day). According to these observers (Freud: "Bemerkungen über Cocainsucht und Cocainfurcht," *Wiener Med. Wochenschr.*, xxxvii., No. 28, 1887) the cocaine habit is not to be feared, as persons, unless they are addicted to the opium habit, can discontiuue the use of cocaine without any symptoms therefrom. Preparations of coca in the form of coca wine are extensively advertised and used as a nerve stimulant.

In whooping-cough applications of two to five per cent. solutions to the tonsils, pharynx, and epiglottis have been used with good result (Schuirer: *Arch. für Kinderheilkunde*). Various neuralgias and the shooting pains in locomotor ataxia are a field for the subcutaneous application of cocaine. In tabes, 0.02–0.03 twice a day is re-

ported to have succeeded in cases where morphine did not have the desired effect. Cocaine has also been recommended in sea-sickness, however with little success.

Opium Habit.—The recommendation (Freud: *Centralblatt für Therapie*, July number, 1884) to use cocaine in the cure of the opium habit did not meet with general approval, on account of the danger of making the subjects of the opium habit victims of the cocaine habit in addition. As Freud ("Bemerkungen über Cocainsucht and Cocainfurcht," *Wr. Med. W.*, 1887, No. 28) believes, cocaine is a very valuable agent to combat the craving for morphine and the collapse incidental to the disuse, provided the physician absolutely controls the administration. Obersteiner considers the use of cocaine admissible if no morphine at all is given. He recommends to administer it only internally, the first dose 24–48 hours after the last dose of morphine, giving about 0.05–0.1 several times a day, and not more than 0.5 per day, gradually diminishing the quantity and stopping the administration on the fifth or sixth day.

Accidental Poisoning.—It is not surprising that a drug which came into such rapid and general use in almost all branches of medicine and surgery, should have given rise to many and even fatal accidents, partly due to lack of acquaintance with the drug, and partly due to recklessness. The history of cocaine poisoning has already developed quite a literature. Its more judicious use in recent years has greatly reduced the frequency of such accidents. Cases of slight poisoning, which are the commoner ones, offer the following objective symptoms: Pallor, cold perspiration, frequent pulse, dilated pupils; subjectively the patients complain of dryness of the throat and the lips, a feeling of heaviness in the limbs, weakness, or even vertigo. This condition does not last long, and after a short time (one-half to one hour) complete well-being sets in, although no restoratives are used. In another class of more serious accidents great mental excitement, with talkativeness, hallucinations, and even delirium, can be present. On the other hand, conditions of syncope and collapse can prevail. In the gravest cases painful dyspnoic breathing, clonic and tonic convulsions occur, which can cause death by tetanus of the respiratory muscles. Or death can result from paralysis of respiration and heart without preceding convulsions. Dr. Paul Mannheim, under the guidance of Leyden, has made a thorough compilation of the accidents hitherto reported in medical literature ("Ueber das Cocain und seine Gefahren in physiologischer, toxicologischer und therapeutischer Beziehung," *Zeitschrift für klinische Medicin*, xviii., 3 and 4, pag. 380, 1891). The discussion in the Société de Chirurgie de Paris of a fatal case reported by Dr. Paul Berger, is also of great interest and rich in information ("Empoisonnement mortel produit par l'injection d'une Solution de Chlorhydrate de Cocaine dans la tunique vaginale à la suite de la ponction d'une hydrocèle," *Bulletin et Mémoirs de la Soc. de Chir. de Paris*, 1889, pp. 751, 757, 761, 790).

Mannheim has collected ninety-nine cases from the literature in which the doses used, the symptoms, etc., were stated with sufficient accuracy, and the following account is based upon these cases. The statement frequently made that weak and nervous women are more inclined to constitutional symptoms cannot be accepted; sex does not show any influence. Idiosyncrasy cannot be proven to play a part (the writer fully concurs in this opinion). Although idiosyncrasy against alkaloids certainly exists as a rare exception, it will not do to assume such peculiarity in every case where a quantity, harmless to one individual, produces constitutional symptoms in another. There are other circumstances that should be taken into consideration, for instance, the velocity with which a given amount is thrown into the general circulation. The same quantity in a more concentrated solution will be more quickly absorbed than if dissolved in more water; a tissue richer in blood-vessels will absorb faster than a less vascularized one, etc. For similar reasons it may be that constitutional symptoms occur with relative frequency in operations on the head, which fact has been especially emphasized by Wölfler ("Zur toxischen Wirkung des Cocain," *Wien. Med. Wochenschr.*, xxxix., 18, 1889) and explained by the nearness of the brain). The sitting posture has been accused as especially aiding the anæmia of the brain, supposed to be the chief cause of the weakness and vertigo in the minor cases. Out of the ninety-nine cases tabled by Mannheim, cocaine was administered hypodermically in fifty-one, instilled in the eye in nine, in the ear in two, brushed on the mucous membrane of the nose in five. Sometimes very small doses produced graver symptoms, sometimes very large doses were followed by very slight ones. The time of appearance of the symptoms varies, being five to ten minutes on an average; sometimes they appeared immediately after administration, or after a few seconds, sometimes only after one-fourth or even one-half hour. In the following the symptoms of poisoning are given as collected by Mannheim from the various cases. (The seeming contradiction in the symptoms is not to be wondered at, if it is taken into consideration that cocaine is a poison with first stimulating and afterward paralyzing properties, and that according to quantity or velocity of absorption the first or the second will prevail.—Writer.)

General Symptoms.—The patients become sleepy and get into a soporous condition; they almost lose consciousness and faculty to articulate, or they fall within a few minutes into a very deep sleep of comatose character. Severe collapse has been observed, preceded by weakness, with complete loss of consciousness of long duration and with reduced respiration. In other cases the patients become very restless and excited, seem dizzy, cry and laugh alternately, gesticulate, and are very talkative, not heeding any questions put to them; incessantly change their position, stand up, sit down; their gait becomes unsteady, like that of a drunken person. This condition grows into intoxication, or a feeling of impending death. There may be sleeplessness, lasting from thirty to forty hours; afterward complete forgetfulness of what has happened.

Central Nervous System.—In mild cases reflexes are increased, cerebral irritation and delirium, lasting as much as an hour, hallucinations. In severe cases epileptiform attacks, with general clonic convulsions, lasting even five hours, tetanus, opisthotonos, death.

Peripheral Nerves.—Sensibility diminished. Complaints of loss of sensation on the whole body or on single parts, limbs, or pharynx. Sometimes only numbness, sometimes complete anæsthesia. Feeling of intense coldness in the anæsthesic parts. Various paræsthesias. On the part of motor nerves twitching of single muscles (or as already mentioned, general convulsions), in other cases heaviness or tired feeling in the limbs, sometimes aggravated to apparent paresis. Gait staggering or complete inability to walk.

Eye.—Pupils dilated, sometimes very contracted; reacting in some cases, in others motionless. Some patients complain of darkness before the eyes, others notice diminished acuteness of vision, complain of mist before the eyes; in some instances complete amaurosis (transient). One lady recovered vision only after four hours.

Other Special Senses.—Buzzing in the ears, various disturbances of smell and taste.

Respiration.—Short, whistling, laboring. Paroxysms of dyspnœa. On the contrary, the frequency can be diminished (even to nine respirations in the minute) and may cease, so that death occurs by asphyxia. Sometimes Cheyne-Stokes respiration has been observed.

Circulation.—Pulse very accelerated, often very weak, filiform, irregular, at last hardly, or not at all perceptible. In other cases, pulse less frequent. Diuresis increased according to some writers, diminished and even suppressed according to others.

Organs of Digestion.—Numbness of the throat, astringed sensation and dryness in the pharynx, dysphagia. Burning pain in mouth and stomach (even after hypodermic administration). Pain in intestines. Rectal and vesical tenesmus.

Cause of Death.—Paralysis of respiratory and vasomotor centres and heart, whereas in other cases death results from tetanus of respiratory muscles.

Autopsy showed, in the few cases examined, intense hyperæmia of the brain and of the inner organs.

Fatal Dose.—In five of the fatal cases the dose was larger than one gramme, whereas only one patient who had been given one and one-fourth gramme recovered. From this Mannheim concludes that one gramme is to be considered the fatal dose.

Of the 99 cases thus compiled, 9 were fatal. Besides, there are 100 cases in literature where no symptoms are mentioned. Of Mattison's 108 cases, 58 are included in Mannheim's table, whereas 50 are not. This makes altogether 250 cases with 13 fatal results, so that of the accidents reported five per cent. proved fatal. (Considering that most of the graver and fatal cases are reported, while the much more frequent minor accidents do not come to general cognizance, the figure five per cent. is certainly too high.—K.)

Treatment of Cocaine Poisoning.—In the minor cases, where weakness and dizziness prevail, horizontal position of the patient and administration of stimulants, like brandy, coffee, ether, are the reasonable measures to be taken. Inhalation of a few drops of amyl nitrite has been recommended, and is the measure generally adopted to combat the supposed anæmia of the brain. For the severe cases, where convulsions occur, Mosso, from his experiments on dogs, comes to the following conclusion: "If it were necessary to assist a human being poisoned with cocaine, one would have immediately to resort to ether or chloroform to prevent tetanus of the respiratory muscles, which is the most frequent and dangerous cause of death. After the first grave and imminent danger has passed, chloral can be given. If respiration stops, artificial respiration must be resorted to."

Dose.—Internally 0.02 to 0.05 gramme several times a day can be considered a safe dose, and even 0.1 may be given. For hypodermic use in operations it is advisable to keep under the 0.05 limit. Weak solutions of one per cent. and two per cent. should be used, well distributed over the field of operation. For spraying (nose, throat) weak solutions (two per cent.) should be used in known quantity. For operations in nose, pharynx, and larynx, brushing with strong solutions cannot be avoided, but in these cases the danger is obviously less, because the quantities used are small. Careful watching of the patient and gradual administration in all cases will increase the safety of continued administration.

Cocaine Habit.—Most subjects of the cocaine habit are victims of the opium habit who have taken cocaine for the purpose of curing themselves, have not succeeded in their efforts, and have consequently become addicted to both drugs. It is therefore not easy to state the symptoms of the cocaine habit pure and simple. Luff (London *Lancet*, September, 1889) tells of a man who used 0.25 gramme daily during three years for nasal catarrh, and who, in consequence, was very much reduced physically, mentally, and morally. He became unsociable, incapable of attending to his business, because unable to come to any decision. Palpitations of the heart, obstinate constipation. Bauer (New York *Medical Record*, November, 1885) tells of a man who replaced the use of alcohol by daily injection of 0.67 gramme cocaine. He became very weak, lost all appetite; had attacks of delirium; ultimately complete physical and mental decay.

From all observation it appears that rapid falling off in flesh is one of the most prominent somatic symptoms of the cocaine habit. Erlenmeyer (*Deutsche Medic. Zeitung*, 1886, page 483) reports a falling off of twenty to thirty per cent. within a few weeks, without diminution of food and with no existing catarrh of the stomach. He lays great stress on the respiratory and vaso-motor disturbances caused by the blood-vessel paralyzing properties of cocaine: frequent pulse, relaxation of arterial system, profuse perspiration, syncope. The psychical symptoms are very marked and characteristic, and in well-developed cases offer the clinical picture of hallucinatory paranoia. They consist, according to Obersteiner, chiefly of feelings of fright caused by hallucinations, especially in the visual and sensory sphere. Either terrible apparitions are seen or great hordes of small animals. These latter hallucinations are most likely based on itching paræsthesias of the skin, giving to the patient the impression of the presence of insects or worms under the skin and causing him to scratch. There exists an interesting observation of Ehrlich's, in his experiments with mice above mentioned, which closely recalls these paræsthesias and hallucinations based upon them. One of his mice, after three weeks' use of cocaine, began to gnaw its limb, so that in the course of the next days the whole right thigh down to the knee was entirely denuded. Ehrlich's explanation of this remarkable fact is that paræsthesias due to degeneration of the peripheral nerves provoke the gnawing, while the simultaneous anæsthesia of the skin leaves the latter without the protection of sensation.

While some writers deny the existence of symptoms due to withdrawal of cocaine in cases of well-formed habit, others, like Obersteiner and Erlenmeyer, affirm the contrary. According to Obersteiner they frequently appear only after the lapse of a fortnight and consist of sudden collapse and a feeling of impending death. Erlenmeyer emphasizes the vaso-motor disturbances as palpitation, weakness of the heart, dyspnœa, syncope, depression of humor, enormous weakening of the will power. According to all writers the prognosis of the cocaine habit is not a good one, as patients very readily relapse.

Carl Koller.

COCILLANA. A plant belonging to the order Meliaceæ, indigenous to tropical America. Its use was advocated for its expectorant properties by Professor H. H. Rusby in 1886. It is obtained from Bolivia, where it is employed as an emetic and purgative. The root is the part used, from which is prepared a tincture, one part in six, and a fluid extract. The dose of the former is from one-half to two drachms, and of the latter five to twenty minims. The powder is not used, as it produces sneezing, coryza, and irritation of the mucous membrane of the nose and throat and pulmonary tract. In overdoses it produces emesis, and causes gastric and intestinal irritation. As an expectorant it acts within half an hour, stimulating the secretion of the bronchial mucous membrane and producing a free flow of mucus; this continues for some hours, and is followed by diminished activity of the glands. It has very little action on the skin. It has proved of greatest service in chronic and subacute bronchitis when the secretion is scanty and tenacious. In such cases it liquefies the secretion and stimulates expectoration. The fluid extract, in doses of ten minims every three or four hours, seems to have been the most serviceable means of securing its effects. In the early stages of acute inflammation it should not be given. In bronchorrhœa and in the aged with profuse secretion it is not advised, as it does not stimulate the respiratory organs, and might produce too free secretion within the tubes. In phthisis it has to be used with caution on account of its irritant action upon the digestive tract, and the danger of producing inflammatory foci in the lungs.

Beaumont Small.

CŒLIOTOMY, DRAINAGE AFTER. As early as 1856 Dr. Peaslee advocated the use, after cœliotomy (laparotomy), of a rubber drainage-tube which should pass from the lower angle of the abdominal wound downward and through an artificial opening made from the bottom of Douglas's pouch into the vagina. He irrigated through this tube, from above downward. His success was satisfactory, but the practice fell into disuse, because a little later a glass tube began to be substituted for the rubber, although it was allowed to pass in only to Douglas's pouch. About this time Lister was teaching us our first lessons in antiseptic surgery. The short or long glass tube, as was needed, proved much more useful than the rubber had in the earlier attempts at drainage, not because of a better principle, but rather because of improvement in the antiseptic methods in doing the work.

Peaslee's ideas of drainage were correct, as we look back at his work to-day. But we know better now how

much to trust to nature and how much to drainage. Later still, in 1886, the method of packing any part of the abdominal cavity which was denuded of its normal peritoneum, with a quantity of aseptic gauze, was advocated. This practice, without doubt, has served to save the lives of many patients.

There are always possibilities of danger in the use of drainage-tubes: (1) In the fact that the operator can, or may, do a hasty or an imperfect operation, with the consciousness that the subsequent use of the drainage-tube will avert all danger; (2) because in the after-treatment sepsis may be conveyed directly to the wound by means of the tube itself; (3) because of the extra liability to ventral hernia when the tube is used.

That a drainage-tube, or drainage-gauze, should ever be needed is clear proof that surgical work in the abdominal or pelvic cavity cannot be done after an ideal method. Any drainage after an operation means imperfect work. In other words, we have not removed all possible sources of sepsis; we have not checked all bleeding from small vessels; we have tied arteries which will destroy the vitality of certain sections of tissue; we have broken up adhesions, and have not protected these raw surfaces in a kindly manner; we have left the pedicle insecure.

These indications existing, and with the very best surgery, it is necessary to reduce the dangerous results of such imperfect work to a minimum. To do this we must not neglect any precaution which, in our judgment, is necessary, or which is well known to be of absolute service. The latest method of operating upon a table which will easily allow the patient to be placed in the Trendelenburg posture, and in a room where a strong electric light can be used in the exploration of the cavity after the tumor has been removed, has rendered the subsequent use of a drainage-tube, in many of its previous forms, quite unnecessary. For with these methods, other things being equal, every bleeding vessel should be detected as surely as though it was on the face of the patient.

This ability to see into the cavity thoroughly also renders the operator far less likely to rupture, in removal, the small or large septic tumor. And so, also, the adhesions are dealt with more gently when all can be seen by the eye as well as felt by the finger; facilities which the new posture and the electric, or strong, light afford. To-day, therefore, when the operator is aseptic, the field of operation aseptic, and the surgical implements aseptic, the table and the light as nearly perfect as can possibly be obtained, we have far less need of the drainage-tube and are nearing our ideal operation. But, as we have not yet attained to this ideal standard, we must, for the present, resort sometimes to the best method for drainage.

The several methods of drainage may be quickly described. The glass tube is the one which has been most frequently and most successfully used during the last ten years. The tube, if needed at all, should be from three-quarters to one inch in diameter and from four to six inches in length; it should be open at the distal end and have several side perforations near this end. It is not necessary for the tube to be curved, as was formerly believed to be important. This glass tube should be placed so that the distal end will rest very near to the probable or possible future location of sepsis, the proximal end resting in the lower angle of the abdominal wound. One suture should always be inserted here, and left untied, for the special purpose of closing this track as soon as the glass tube is removed. The tube should be loosely packed with sterilized gauze, which, at the proximal end of the tube, should be covered with a compress of soft, sterilized, absorbent cotton. The tube should be dressed from time to time, according to the rapidity with which the gauze becomes saturated from within, and should be removed just as soon as the fluid which escapes is found to be scant and benign in character.

The drainage should take place through iodoform gauze in all septic cases, as it will be necessary to retain the glass tube *in situ* for from four to six days. In case the packing is only to check a hemorrhage from small vessels, and surfaces from which the peritoneum has been removed, common sterilized gauze will suffice, as such packing can soon be safely removed.

For pockets beneath the broad ligaments, or low down in Douglas's pouch, counter-drainage should be instituted through the vagina. The gauze should be from one and one-half inch to two inches wide and from two and one-half to ten yards in length. The distal end should be passed through an opening, which can be most easily and directly made into the vagina. The opening can be made with a trocar, or forceps, or scissors, from above downward, the finger in the aseptic vagina indicating the locality of the least amount of tissue to be penetrated, care being taken at the same time to avoid the ureters and uterine arteries. An iodoform gauze tampon should be inserted in the vagina. The proximal end of the drainage-gauze should be carefully and methodically laid in, fold on fold, or coil after coil; and finally it should be crowded into the cavity which is to receive it.

If it is possible, the slit in the broad ligament, or the parts above Douglas's "pouch," should be closed with catgut sutures, thus completely shutting off the gauze from the abdominal cavity. Of course, after making a counter-opening into the vagina there must be a thorough irrigation, with sterilized water, through the lower pelvis and out through the vagina, before the gauze is inserted.

The following are the notes of two of my own cases treated in this manner:

Case 1. Mrs. H., in my service at the Woman's Hospital, 1891. She had physical and symptomatic evidence of a cyst in the true pelvis, under the broad ligament. There had been exacerbation and remission of fever, her physician informed me, before she entered the hospital. I found, on operating, that the left ovary had been displaced backward, and after being completely covered by the broad ligament and an exudate, an ovarian cyst had developed, over three inches in diameter. Splitting through the exudate, I emptied the cyst with the aspirating needle. Its contents were purulent. I then enucleated and cut away the larger part of the cyst, but the lower zone was so tightly adherent to the cellular tissue which formed its bed, that the question of time for removal of all this friable, septic material had to be considered. As there was but a thin wall of tissue between this part of the cyst and the vagina, I quickly decided to drain into the vagina. I placed, therefore, a long piece of gauze in the jaws of a somewhat sharp-pointed pair of forceps, and then pushed this instrument through the lowest portion of the cyst which I had been unable to remove, directly through into the vagina just back of the cervix. I will mention here that in my service the vagina is always made aseptic before cœliotomy. I then irrigated through this opening. The remaining gauze I carefully laid in the cavity just occupied by the cyst and firmly crowded it down.

All went well for two weeks. At the expiration of that time I thought I could safely remove the drainage-gauze, and did so. The temperature and pain soon convinced me that the drainage should be continued for a longer period. I therefore inserted a rubber drainage-tube for an inch and a half into the sinus, and fastened it *in situ* by means of a silver-wire suture. This was retained in place, and irrigation was kept up through it for nearly four weeks, with the result that the patient at the end of that time was discharged cured.

Case 2. Mrs. M., thirty years of age, in my private sanatorium, 1892. A suppurating cyst, three by four inches, was found developed beneath the broad ligament. The ovary and tube on the same side were both diseased and displaced backward, and covered with an exudate. An incision directly through the broad ligament laid bare the tumor. The cyst was so friable that I had to remove it in small pieces, and then I could not be sure but that some portion had been left. To have painted this cavity with a germicide sufficiently strong to kill all possible septic elements remaining, or to have

burned this large surface with the thermo-cautery for a similar purpose, would have exposed the patient to a greater danger than that which the tumor itself would have afforded had it been left undisturbed.

I therefore passed the points of a pair of scissors directly through into the aseptic vagina, irrigated through this canal, then pushed the end of the gauze into the vagina, and carefully coiled the remaining portion of the gauze in the nest formerly occupied by the cyst. The tube and ovary on the same side were then loosened up and removed in the usual manner. I then turned the stump of the pedicle into the incision which I had made in the broad ligament on this side, and closed the slit with catgut, leaving nothing that could possibly cause trouble in the abdominal cavity. The gauze was removed gradually, a few inches at a time daily, and by the tenth day all had been removed. The patient made a perfectly satisfactory recovery, the temperature, after the first day, never rising above 100° F.

The necessities for drainage can be grouped under four heads:

1st. Inability to remove the whole of a septic tumor or tissue, especially when a ligature has passed through such septic tissue.

2d. A large space of granulating surface after enucleation of tumor or separation of adhesions.

3d. A large number of minute bleeding vessels, which, from their location, will require too much time to close.

4th. Fear of secondary hemorrhage.

This last reason should be, and will be, the excuse given only by the timid and inexperienced surgeon. The best surgeon will never leave a pedicle so insecure as to excite fear of hemorrhage, while his catgut or other aseptic ligature material holds out. This fourth excuse for drainage, therefore, may be excluded, and will never be put forward by a judicious operator, when it is understood that any pedicle or ligature can be made absolutely secure at the time of the operation, in one-half the time it will take to prepare the patient for a secondary operation, after the necessity for such operation has been demonstrated by the collapsed condition of the patient, and the other usual signs of secondary hemorrhage; and also when it is remembered that all patients are far better able to remain on the operating-table for the five or ten minutes necessary to strengthen the original ligature—or for additional ligatures, or a half-dozen deep catgut sutures, introduced with a full-curved, round-pointed needle—*before a secondary hemorrhage* than after it has occurred.

Let us carefully consider the other reasons for drainage:

1. The necessity for keeping a drainage-tube, or gauze, at the site of sepsis will be admitted by all. And we all know that sometimes the condition of our patient will not allow us to carefully curette every septic cavity, even if we were absolutely positive of entirely removing the possible source of sepsis; and in the true pelvis or under the broad ligaments we are never absolutely certain that we have removed everything septic. Other things being equal, time is a great factor in the ultimate results of all major operations, especially in abdominal surgery. If, however, such septic surface is far from the abdominal wound, and near the vagina, drainage *through* the vagina, as described, would be indicated and should be preferred.

But when there is need of drainage because of sepsis, or fear of sepsis, and the lowest point of contact for such sepsis is not far from the lower part of the abdominal opening, a glass tube, or a gauze bag, three by six inches, filled with sterilized or iodoform gauze, and inserted in the lower angle of the abdominal wound, will serve best. I am inclined to use the latter method in tubercular peritonitis and tubercular salpingitis, and when a large septic tumor has had to be enucleated from its bed near the normal position of the fundus uteri. The former method, the glass drainage-tube, is preferable where sepsis is feared over only a small space, like the condition present when a very badly diseased tube, or small ovarian abscess, has been operated upon.

2. In really non-septic cases, if there are many adhesions broken up and separated, or when there is a large raw surface left in the cavity after enucleating, we must expect much sweating of serum, and we always fear adhesions of the intestines to the bed from which the tumor has been removed. In such cases, if we cannot close this large raw surface with a few catgut sutures, and thus shut it off from the abdominal cavity, and after dusting the intestines (when adhesions have existed) with aristol powder, we still find the parts too much inflamed to warrant our trusting to nature's efforts alone, then we must place the bag of gauze in the abdominal wound or the gauze in the vagina, choosing the one or the other, as may seem most judicious.

3. In those difficult cases where there is a somewhat threatening, or at least a continuous, oozing of blood from the lower pelvis, after an enucleation of a solid or semi-solid tumor, if these vessels cannot be seen and closed by pressure, or the hemorrhage is not checked by hot water, nor by dusting with sterilized powdered persulphate of iron, then there is nothing to do but to fill the bleeding space with gauze. First the gauze bag, then packing this bag tightly with gauze from above, and, if we are not then satisfied with the state of things, buttressing the gauze with a firm tampon in the vagina.

4. My firm belief, for reasons given above, is that we should never drain simply because we fear secondary hemorrhage from a large vessel in the pedicle.

Too much attention to cleanliness cannot be exercised in managing the tube. In septic cases, after watching the contents of the tube for four or five days, a smaller tube may be used, and generally within a week this can be removed, and the track of the tube be closed by tightening the suture.

When drainage is resorted to for the purpose of removing the serum from sweating raw surfaces, within twenty-four hours the gauze, or the glass tube, should be partially removed, and altogether withdrawn by the end of the second day. In counter-drainage through the vagina a piece of gauze, from three to five yards long and from one and a half inch to four inches wide, should be used, and should be withdrawn through the vagina, little by little, daily, until all is removed. When the last is taken away the cavity should be thoroughly irrigated. If there is still evidence of pus a rubber drainage-tube should be inserted into the blind fistula, and retained by one of the several methods in general use. All tubes and all gauze must be thoroughly sterilized. If gauze is to be kept *in situ* for a week, sterilized iodoform gauze remains less offensive when in use than plain gauze sterilized. But when the gauze can be frequently changed, plain sterilized gauze is perfectly satisfactory.

Horace Tracy Hanks.

CŒLOM. In all vertebrates the primitive intestine forms two sets of diverticula which are destined to become permanent tissues, (1) one toward the medullary groove which forms the chorda dorsalis, and (2) two lateral diverticula which form the body cavities. These latter are later on subdivided into pleural, pericardial, peritoneal, and other cavities. A detailed description of the theory of the formation may be found in Balfour's work, in Hertwig's "Embryologie," in Minot's "Human Embryology," and in Minot's article, "Fœtus," in Vol. III. of this HANDBOOK.

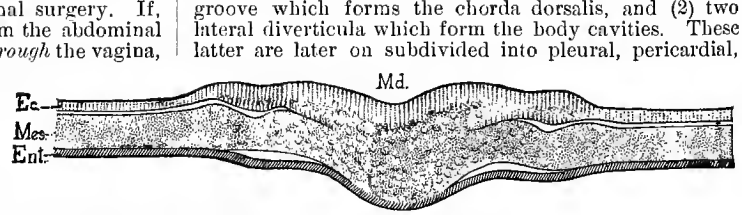


FIG. 100.—Transverse Section through the Posterior Region of a Chick, with Six Pairs of Myotomes. (After Waldeyer, from Minot.) *Ec.*, ectoderm; *Mes.*, mesoderm; *Ent.*, entoderm; *Md.*, medullary groove.

When sections are made through very young embryos of higher vertebrates, just after the blastodermic membranes are well formed, a solid mesoderm is present, as shown in Fig. 100. Although in lower vertebrates the mesoderm is produced by lateral diverticula from the entoderm, which are hollow from the beginning, in higher vertebrates the mesoderm is first laid down as a solid mass of cells. Soon the cells of the mesoderm on either side of the chorda divide into two layers, the somatopleure and the splanchnopleure (Fig. 101, *Som.* and *Spl.*). It is from these two lateral cavities that the peritoneal cavity is formed.

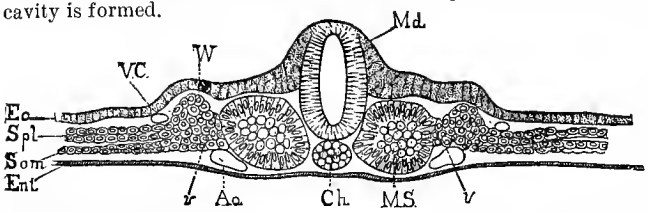

FIG. 101.—Transverse Section of a Chick of the Second Day. (After Waldeyer, from Minot.) *Som.*, somatic mesoderm; *Spl.*, splanchnic mesoderm; *Ec.*, ectoderm; *Ent.*, entoderm: *V.C.*, vein; *W.*, Wolffian duct; *Md.*, medullary canal; *Ao.*, aorta; *Ch.*, chorda; *M.S.*, myotome.

The more accurate early formation of the pleuro-peritoneal cavity, in its relation to the other organs, we find carefully studied by Budge, who by means of injection followed it in the chick. With a fine hypodermic syringe he filled the various spaces of the cœlom as they appeared, thus showing very clearly the extent of this cavity in various embryos. The splanchnopleure, according to Budge, may be split into two layers, a dorsal or lymphatic and a ventral or vascular. As the first blood-vessels are formed, lymph-vessels appear on their dorsal side, which flow together to form net-works and accompany the primitive veins to the axial part of the germinal area. Here the lymphatics form two spaces, one on either side of the body, which are soon united by a bridge, or rather duct, on the ventral side of the heart. In this way, in birds at least, this primitive pleuro-peritoneal cavity appears somewhat as an H, the uprights of which are on either side of the body, and the cross-piece a cross-section from a chick at this stage, and shows that the greater portion of the cavity is now on the outside of the body. The cross-piece of the H is immediately on the ventral side of the heart, and forms the cavity of the pericardium by the heart growing into it. Its communication with the remaining cœlomic cavity is later on cut off in higher vertebrates, while in lower vertebrates it may remain open.

According to Budge two diverticula grow from the cross-piece, one on either side of the chorda, toward the tail of the body, and form the primitive pleuro-peritoneal cavities. Budge's paper was published from fragmentary notes after his death, and I am sure that the above statement is not correct. Professor His has placed before me Budge's specimens, which I think show conclusively that his interpretations of his injections are not correct. Most of his injections were made into the amniotic fold as the amnion was forming. Cross-sections of embryos show that on either side there is a large cavity (Fig. 102, *Som.*) which communicates freely with the pleuro-peritoneal (*Coe*). Before the amnion is complete we have lateral cavities on either side of the body, communicating with each other only by means of the cross-piece on the ventral side of the heart. This is the freest portion of the communication, which also communicates most freely with the pleuro-peritoneal cavities (Fig. 102, *Coe.*). In many embryos the injection passed from the cross-piece into the pleuro-peritoneal cavity and would not extend out into the amniotic portion of the cœlom, thus making it appear as if the pleuro-peritoneal cavities were, so to speak, diverticula projecting directly from the cross-piece or pericardial cavity. Transverse sections, however, give the picture of Fig. 103. Surface views could not decide that these two cavities

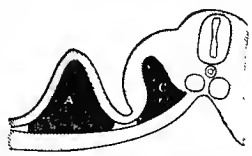

FIG. 103.—Section of a Chick, to show that the Pleuro-peritoneal Cavity is cut off of the Cœlomic, leaving a Portion in the Amnion. The embryo has been injected, but the fluid of the two cavities has not flowed together.

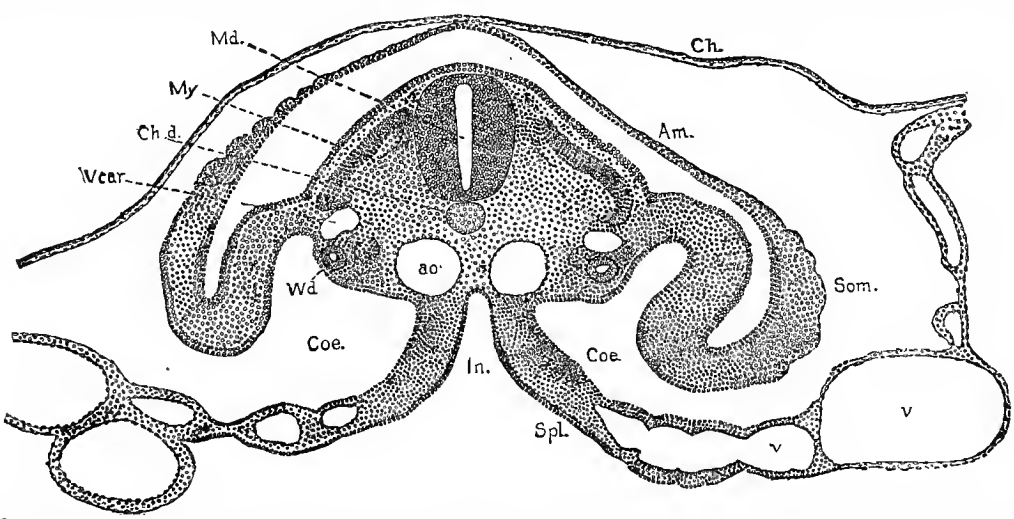

FIG. 102.—Section through the Body of a Chick of the Third Day. (After Minot.) *Ch.*, chorion; *Am.*, amnion; *Som.*, somatopleure; *v.*, blood-vessels; *Coe.*, cœlom; *Spl.*, splanchnopleure; *In.*, intestine; *ao.*, aorta; *Wd.*, Wolffian duct; *Vcar.*, vena cardinalis; *Ch.d.*, chorda dorsalis; *My.*, myotome; *Md.*, medullary canal.

on the oral side of the sinus venosus. In its further development the sinus venosus grows to the dorsal side of the cross-piece, thus reversing the relation of the vascular system to the lymphatic, or rather cœlomic system. The uprights of the H fall to the outside of the body and are swallowed up in the formation of the amnion. Fig. 102 is united directly, and these sections were no doubt made after the writing of the rough draft of his manuscript. Therefore, instead of stating that the two pleuro-peritoneal cavities arise as independent diverticula, we must say that they are pinched off from the cœlomic cavity after the amnion is formed.

The cœlomic cavities which are so intimately united with the lymphatic system, unite and again divide into sections, thus forming the various compartments of the visceral cavity of higher vertebrates. In all of the vertebrates the heart, as it is developing, hangs into the ventral transverse portion of the cavity, or the primitive pericardial cavity. This is shown diagrammatically in Figs. 104, 105, 106, and 107, *P.*

Figs. 104 to 107 show the very early condition of things; the cœlomic cavities are united by the cross-piece or the

FIGS. 104, 105, 106, and 107.—Diagrams to Show the Development of the Cœlomic Cavity. *P.P.*, pleuro-peritoneal cavity; *A.P.*, portion of the cœlomic cavity swallowed up in the amnion; *P.*, pericardial cavity; *L.*, pleural cavity; *G.M.*, gastric diverticula, right and left; *D.*, position of the diaphragm; *L.G.D.*, left gastric diverticulum; *R.G.D.*, right gastric diverticulum or lesser peritoneal cavity; *F.W.*, foramen of Winslow; *G.P.C.*, greater peritoneal cavity; *T.*, tunica vaginalis.

primitive pericardial cavity. The dotted lines (Fig. 104), mark what portion of the cavity is taken up in the amnion (*A.P.*), while the remaining middle portion (*P.P.*) becomes the pleuro-peritoneal. Figs. 105, 106 and 107 show in succession the more advanced stages. In higher vertebrates the pericardial cavity is completely closed off from the pleuro-peritoneal, but in elasmobranch fishes a communication between them exists in the adult. The separation of the pericardial cavity from the pleuro-peritoneal is aided materially by the heart going over to the ventral side of the body, as shown in Fig. 108. Sections through various parts of the same embryo, from which Fig. 108 is taken, are shown in Figs. 109 to 114. In none of these sections is the communication between the pericardial and pleural cavities shown, but sections nearer the head contain it.

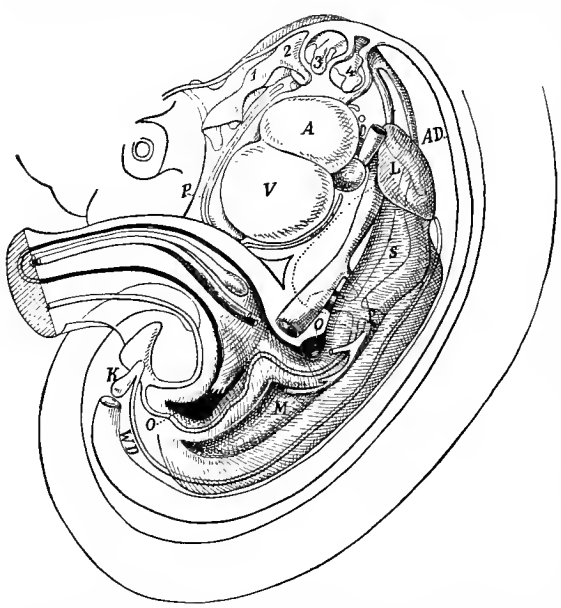

FIG. 108.—Reconstruction of a Human Embryo. (Enlarged 16 times, viewed from the left side.) *P.*, pericardial cavity; 1, 2, 3, and 4, branchial pockets; *A.D.*, descending aorta; *A.*, auricle; *V.*, ventricle; *L.*, lung; *S.*, stomach; *P.*, pancreas; *M.*, mesentery; *K.*, kidney; *W.D.*, Wolffian duct; *O.*, openings through which the right and left peritoneal cavities communicate.

A cast of the cœlomic cavity of this same embryo is given in Fig. 115. There is only a slight communication between the pericardial cavity and the pleuro-peritoneal. The groove in the cast marked *M* indicates the position of the simple mesentery. Its relation to these organs is better shown in the sections (Figs. 109 to 114). Fig. 116 represents a section through a chick at an earlier stage of development, in which the duct communicating between the pericardial and pleural cavities is cut longitudinally. Thus it is seen that the heart first grows into the primitive pericardial cavity, which is nothing else than the cross-piece of the H already spoken of. The heart grows larger and larger, at the same time hanging as it were over the ventral side of the body, and is soon connected with the pleuro-peritoneal cavity only by two ducts, which later on become closed in the higher vertebrates.

In early embryos the veins enter the heart behind, and not in front, as is the case in higher animals. The heart in its whole development undergoes a half revolution, and in this way the twists, etc., are formed.

Before the pericardial cavity is shut off from the pleuro-peritoneal the large vessels enter from behind. They are embedded in a mass of mesoblastic tissue which is encroaching upon the pleuro-peritoneal cavity, and has been termed by His the transverse septum. This, by its further growth, forms the diaphragm of higher animals (Figs. 105, 106, 107). In lower animals only a rudimentary diaphragm, or none at all, is present. By the formation of the diaphragm the pleuro-peritoneal cavity is divided into a smaller anterior portion, the pleural, and a larger posterior portion, the peritoneal. The lungs now grow into the pleural, as shown in an early stage in Fig. 116, and in a somewhat later stage in Fig. 109.

The peritoneal cavity is at first composed of two distinct portions, one on either side of the intestine, which in lower animals is quite a straight tube, lying in the middle line of the body. Soon, however, two communications are found between the two halves, one in front and one behind the omphalo-mesenteric vessels (Fig. 115, *O.*) These openings enlarge more and more as the intestine becomes more convoluted, and soon flow together, severing completely the omphalo-mesenteric vessels and duct. A portion of the duct may, however, remain in connection with the small intestine to form the diverticulum of Meckel.

As the organs grow the peritoneal cavity surrounds them more or less completely, until the condition of things as seen in the adult is produced.

In lower vertebrates the peritoneal cavity remains quite simple, but in reptiles, birds, and mammals it may become quite complex. Especially is this true regarding the birds, in which these divisions are greatly complicated by the growth of the air-sacs from the lungs.

The first trace of the lesser peritoneal cavity is seen in the reptiles. Ravn has shown that in the lizard there are two diverticula from the peritoneum, one on either side of the stomach. From the one on the right side the lesser peritoneal cavity of mammals arises. In general the relations of the lesser peritoneal cavity to the greater is much like what is shown in Fig. 105. In the true sense of the term there is no lesser cavity, but only the two pouches. These are already present in the embryo, and in the adult they retain their embryonic appearance.

In birds the conditions become more complex. They appear in the chick during the third day of incubation. A section of the chick at this stage is given in Fig. 116, *G.D.*, making the lesser cavities, or, as they may better be termed, the right and left gastric diverticula. At the beginning of the fourth day the gastric diverticula be-

come larger, and on tranverse section semicircular. Figs. 117 and 118 are from casts of the cavities about the stomach of a chick of eighty-eight hours. The right is larger than the left and is markedly cup-shaped, and connects by means of a narrowed opening with the right pleuro-peritoneal cavity (Fig. 117, *F. W.*). The two together enclose the proventriculus. On account of the relations of the opening of the right diverticulum with the blood-vessels, stomach, and liver, and also for reasons which find their basis in comparative anatomy and embryology, the opening can be nothing else than the foramen of Winslow.

On the left side the gastric diverticulum is much smaller, and in older embryos it disappears altogether.

In a chick of five days and sixteen hours (Fig. 119) the right gastric diverticulum has about doubled all its dimensions, while the embryonic foramen of Winslow has become much more sharply defined. At this time the liver has greatly increased in size, the right lobe being larger than the left, both lying anterior to the foramen of Winslow. The original position of the liver being behind the foramen, its rotation necessarily carries the hepatic artery and the portal vein around the foramen of Winslow —its adult position. With the growth of the gizzard a space extends from behind the right gastric diverticulum along the dorsal side of this organ, and marks the beginning of the cavity of the great omentum (*O.*). Nearly the whole of the right diverticulum now lies on the left side of the body ; the same position is held by the proventriculus and the gizzard.

The domestic fowl possesses three peritoneal cavities, completely separated from one another, and from one of them the lesser cavity arises. The communication is by means of the foramen of Winslow. After the anterior abdominal walls are removed, two ventral cavities are exposed, separated from each other by a vertical longitudinal septum. Into each of the cavities hangs a lobe of the liver, while into the left the ventral surface of the gizzard projects. On the dorsal side of the liver there are, on each side, three air-sacs—an anterior, a middle, and a posterior. The middle one is the smallest, and the posterior the largest, extending as it does throughout the posterior portion of the abdominal cavity. Each sac communicates by means of a special opening directly into the lungs. By allowing the sacs to collapse we find that a very distinct membrane projects backward from the gizzard and cuts off the portion of the abdominal cavity containing the intestines. This is the "pseudo-epi-

upright, only one gastric diverticulum is found. It is on the right side in Figs. 109 to 114, which are taken from a young human embryo. In each drawing the cœlomic cavity is colored black and the position of the section can be made out by the organs which are cut across in the section. A cast of the cavity is shown in Fig. 115. The portion of the cavity on the right side of the stomach and the liver is shown in Fig. 120, which is taken from a cast also. Figs. 109, 110, and 111 show sections through the gastric diverticulum of Fig. 120, Fig. 111 being through the foramen of Winslow.

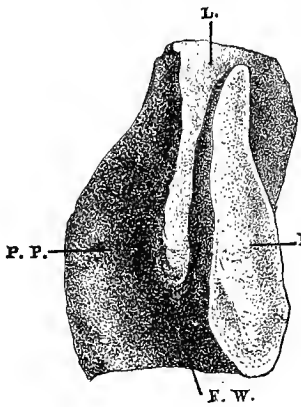

FIG. 117.

FIGS. 117 and 118.—Corrosion Preparations of the Right and Left Gastric Diverticula of a Chick Eighty-eight Hours Old. (× 33 times.) *P.P.*, pleuro-peritoneal cavity; *R.G.D.*, right gastric diverticulum; *L.G.D.*, left gastric diverticulum; *L.*, position of lung; *F. W.*, foramen of Winslow.

the difference that it is adherent to the abdominal walls along its free border. On the dorsal side of the gizzard the air-sacs fill all the space, thus closing off the communication between the cavity in which the intestines lie and the ventral cavities.

FIG. 116. — Section through the Region of the Heart of a Chick of Seventy Hours. (× 35 times.) The section strikes the oral end of the gastric diverticulum *G.D*, and the tips of the pulmonary buds, *L*. A few sections deeper the gastric diverticula communicate with the pleuro-peritoneal cavity. *H.*, heart; *D.C.*, ductus Cuvieri; *B.A.*, bulbus aortæ.

When the anterior and middle air-sacs on the right side are separated from the posterior sac on the same side, a slit is shown which extends anterior and dorsal to the hepatic veins. Here it communicates by means of a round opening, about one centimetre in diameter, with a large cavity lying on the median and dorsal side of the proventriculus and extending to the spleen. The cavity does not extend on the dorsal side of the gizzard. In all respects it corresponds with the right gastric diverticulum of embryos and with the lesser peritoneal cavity of mammals.

The relation of the embryonic omentum with the "pseudo-epiploön" is as yet unknown. However, I think it probable that the one is changed into the other, and that the "pseudo-epiploön" will prove to be the true epiploön homologous with the same in mammals. We must only imagine the embryonic omentum attaching itself on the sides of the abdomen followed by a loss of the epiploönic cavity. A subsequent growth of the air-sacs backward from the dorsal side of the stomach will produce the condition found in the adult.

In mammalian embryos, while the stomach is still

The general form of the cavities is shown in Fig. 120, which is taken from a reconstruction of a human embryo. The peritoneal cavity surrounds the Wolffian body, intestine, omphalo-mesenteric vessels, stomach, liver, and lungs, with the addition of the right gastric diverticulum.

In lower mammals, according to Ravn, there are two diverticula; so the symmetrical arrangement of these

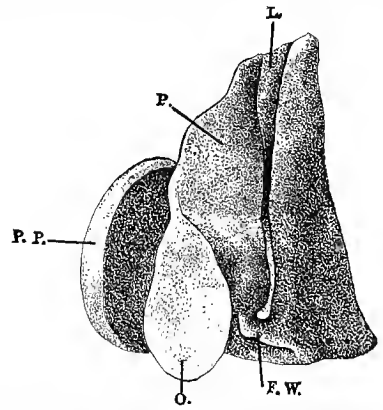

FIG. 119.—Corrosion Preparation of the Right Gastric Diverticulum from a Chick of One Hundred and Thirty-six Hours. (× 15 times). *P.P.*, pleuro-peritoneal cavity; *F. W.*, foramen of Winslow; *L.*, position of right lung; *P.*, position of proventriculus; *O.*, omental cavity (position of gizzard).

cavities in reptiles is still indicated in the mammals. It is so insignificant, however, that we need not take it into consideration.

The fate of the right gastric diverticulum of mammals has been studied in the dog, and it has been found that it is converted directly into the lesser peritoneal cavity, much as is shown in Figs. 106 and 107. In a dog's embryo, six millimetres long, the diverticulum is much like what it

is in the human embryo of about the same size (Fig. 120). A dog embryo, ten millimetres long, shows a picture more advanced, much like what is seen in the chick of five days (Fig. 119). In a later stage (Fig. 121) the stomach has been twisted about, holding in great part the adult position. The liver, which before lay on the ventral side of the stomach, now lies in front, and to a great extent on the dorsal side of it. A model of these parts from a ten-millimetre embryo, simply rotated to throw the stomach away from the mouth, gives the condition of things as they exist in the embryo thirteen millimetres long.

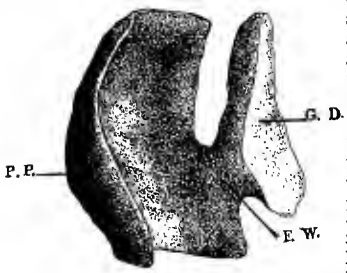

FIG. 120.—Corrosion Preparation of the Gastric Diverticulum of a Human Embryo, 7 mm. long. (× 35 times.) *P.P.*, pleuro-peritoneal cavity; *F.W.*, foramen of Winslow; *G.D.*, gastric diverticulum.

Fig. 121 shows the lesser peritoneal cavity as a cast stuck in behind the stomach. The intestine is composed of two loops, one from the stomach, extending into the pelvis, and the

other from the cæcum into the umbilical cord. The rapid growth of the large intestine has thrown the cæcum as high as the stomach and to the right of it. The fold

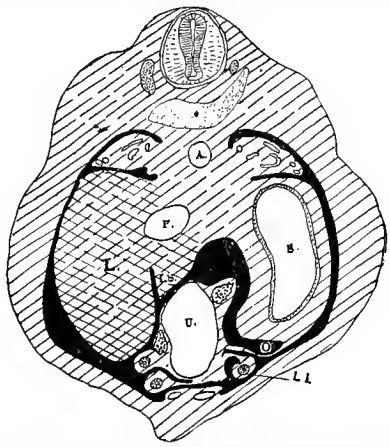

FIG. 122.—Section through the Foramen of Winslow and Lobus Spigelii of a Dog, 13.5 mm. long. (× 36 times.) *A.*, aorta; *S.*, stomach; *P.*, portal vein; *U.*, umbilical vein; *L.S.*, lobus Spigelii; *O.*, omental cavity; *L.I.*, large intestine.

of mesogastrium coming from the dorsal side of the stomach passes over the large intestine to form the omentum (Fig. 121, *O.*). The general shape of the lesser peritoneal cavity is shown in transverse section in Fig. 122, which can be compared with Fig. 111. The S-shaped loop of intestine is cut across three times, and the lesser peritoneal cavity with the foramen of Winslow is shown throughout its whole extent.

The omentum from now on rapidly grows over the whole ventral wall of the abdominal cavity, and in man adheres to the colon as first described by Meckel.

A *résumé* of the subject is given in Figs. 104 to 107.

Franklin P. Mall.

COLBERG. An important watering-place in Pomerania, Germany, near the Baltic Sea. It is also a seaside resort.

ACCESS.—Colberg is a railroad station, and can be readily reached from any European city.

ANALYSIS.—The waters of Colberg are saline, and are chiefly used for brine baths, although they are also administered internally after dilution with carbonated water. The principal springs are the Zillerbergsoole, Marktsoole, and Salinensoole. In 1,000 parts of Salinensoole there are contained:

Chloride of sodium	43.63 parts.
Chloride of calcium	4.37 "
Chloride of magnesium	2.13 "
Sodium bromide	0.04 part.
Carbonate of iron	0.08 "

INDICATIONS.—The place is much frequented owing to the advantages it possesses for sea-bathing, alternating or combined with a course of brine baths. It has been found beneficial in cases of scrofula, anæmia, tedious convalescence after acute diseases, and neurasthenia. Female complaints are successfully treated at Colberg.

ACCOMMODATION.—Good hotels and modern bathing establishments are found here.

Edmund C. Wendt.

CONTAGION. The progress of knowledge of the spreading diseases, in the past six or seven years, has enlarged the sphere of contagion as a factor, and in like degree has diminished that of heredity. (See article on Heredity, in this volume.) At the same time the agency of bacteria in their dissemination has gained greatly in importance with increased research.

Under the present title, in Vol. II. of the HANDBOOK, allusion was made to the ptomaïnes in connection with bacteria. The study of the animal alkaloids has been actively pursued by the German pathologists, with reference to their origin, development, and agency in disease. They are distinguished as *ptomaïnes* when they attend fermentation or putrefaction of a dead animal body, and leucomaïnes when found in living tissues. They result from retrograde metamorphosis, and resemble in composition and character the vegetable alkaloids. The alleged alkaloid of tetanus, for example, has the formula $C_{13}H_{30}N_2O_4$. They are highly unstable compounds in a chemical sense, and consequently difficult to manipulate. Some are toxic; others not so; most are acrid. They are to be regarded as the consequence, but never the cause, of bacteria; and there is good reason to suppose that pathogenic bacteria largely operate through these secondary products.

Brieger and Fränkel (1890) have obtained a ptomaïne from the bacillus of diphtheria, which produced in the animals experimented on precisely the same symptoms which follow inoculation with pure cultures of the same bacillus. Its activity was destroyed by a heat of 140° F. Brieger gives a list of the animal alkaloids isolated up to 1889, amounting to forty-one in all. Wurg has demonstrated (1889) the presence of leucomaïnes in normal blood, and further researches may prove them to be habitually present. Obviously they are not pathogenic, but experiment might show them to be transferable from one healthy individual to another by appropriate culture and inoculation.

CONTREXÉVILLE. This spa, being the most important one of the group in the Vosges district, and being now frequented by many English-speaking invalids, it may be well to give some additional information concerning it. (See also Vol. II. of the HANDBOOK.)

That the waters are the chief point of attraction is not doubted, although the pure invigorating air, the pleasing scenery, as well as the good walks and drives, all contribute to make the place popular and even fashionable. The new railroad has brought Contrexéville to within an eight hours' ride from Paris. Large sums of money have been recently spent upon the thermal establishments, which are now modern and complete in every detail.

Although the *Source du Pavillon* is the spring most generally employed, there are six other springs, all of tried efficacy in the particular line of maladies here treated. The *Source le Clerc*, *Source du Prince*, *Sources Mongeot*, and *Source du Quai*, deserve to be mentioned. All these waters are diuretic, aperient, and at the same time tonic. They disturb the stomach less than the more highly mineralized springs, and have been named "*amis de l'estomac*," in consequence. A statistical table published by Dr. Debout d'Estrées shows that of every hundred patients visiting Contrexéville, on an average thirty-seven suffer from gravel (uric acid, oxalic, or phosphatic), twenty-two from gout, nineteen from vesical catarrh, cystitis, etc., nineteen from gouty diabetes, seven from hepatic colic, and the remaining ten from other chronic diseases of the kidneys, the bladder, the liver, or the stomach (Wolff: "The Watering-places of the Vosges").

The waters of this spa are taken in larger quantities than at the resorts having stronger springs. Patients at Contrexéville are at times directed to take as much as twenty-five glasses a day, which produces a veritable internal flushing. Mr. Wolff summarizes the rules for drinking in this way: "You rise early, to dispose of the prescribed quantity of liquid in good time and with requisite ease. Five or six o'clock sees all the little bathing world assembled round the bubbling spring attractively housed in a neat and roomy pavilion. You drink your tumbler and then take a quarter of an hour's walk—that or thereabouts. Then comes another glass—another walk, and so on. For rainy weather the administration has provided convenient covered walks, sheltered by transparent walls and roofs of glass. In fine weather there is the well-kept little "park," with its gravel walks and its tastefully laid-out turf, and bosquets, and shrubs."

After lunch comes exercise, then perhaps a bath or a moderate potation. Another walk, or lounge, fills up the afternoon, and then comes the six o'clock dinner. In the evening the ordinary amusements are provided, and everybody retires at an early hour. It is in the strict enforcement of regular habits and a suitable régime that the European spas excel our own, and for this reason the therapeutic results seem so much better there. Mr. Wolff notes that the first effect of the water, which is readily assimilated, is to stimulate generally all animal functions. There is a notable acceleration of both pulse and respiration, and a marked diuretic action. All this is not unpleasant. But after a period, in most cases after about a fortnight, but sometimes much sooner, comes the "crisis," rather a trying ordeal. It does not as a rule last beyond from one to three days. Whatever its duration, it makes the patient most decidedly uncomfortable.

In regard to hotel accommodation and lodgings, Contrexéville is now on a level with the better class of French resorts. The season lasts from the middle of May to September. *Edmund C. Wendt.*

CONVALLAMARIN. This glucoside is recommended to replace the other preparations of convallaria majalis, as its dose is more definite and its action more certain and prompt. It possesses all the desired properties as a heart tonic, and is devoid of any irritant action on the bowels and stomach. Convallarin, the other principle of the plant, contains the irritant properties and has been employed for its purgative action. Convallamarin, the chemical composition of which is $C_{23}H_{44}O_{12}$, is a whitish, bitter, amorphous powder, soluble in water and alcohol. Its dose is from one-half to one grain, to be cautiously increased. When administered its action is directed to the muscular structure of the heart; it renders its action more slow by prolonging the period of diastole, which period of rest is followed by a forcible contraction and more thorough emptying of the cavities. When death is produced the heart is arrested in systole. As a cardiac tonic it proves of greatest service in cases where there is a failure of circulation due to organic heart disease; it is indicated where the arterial pressure is reduced, the veins full, and the right side of the heart and lungs are engorged. By the more forcible contractions which its use produces the arteries are filled and the equilibrium of the circulation regained. Where the heart trouble is far advanced, with extreme dilatation and loss of muscular power, the remedy must be given cautiously and its action carefully watched, as the exhausted heart may not be able to maintain the increased effort. The drug is excreted by the kidneys, and at the same time it exerts a direct diuretic action which is supplemented by the increased tension in the vessels, which must also be attributed to the action of the drug. Its advantage over digitalis as a diuretic is its promptness of action, in which it resembles caffeine, and probably it occupies a position intermediate between the two. Although very much praised, it does not prove as efficient in cardiac therapeutics as digitalis, and in no sense supersedes the more used drug; it, however, often proves of value to replace digitalis when it has been given for a prolonged period, and may always be given when digitalis has failed or for other reasons cannot be administered.

Beaumont Small.

CORFU. The most important of the Ionian Islands (Greece), and a popular winter health-resort. Corfu can be reached by way of Trieste in fifty-three hours, and from Brindisi, Italy, in twelve hours. The steamers are moderately comfortable. The climate of Corfu may be considered as typical of the whole group of Ionian Islands. It is a warm place, having a mean annual temperature of 65° F. But the winter months, which represent the invalids' season, average 53° F. Corfu has a moist, marine climate, although when the wind blows from the north extreme dryness may be the temporary result. Rain falls in almost every month, but during the seven cooler months only eighty rainy days occur on an average.

The capital (26,000 inhabitants) of the island is also called Corfu. It is well sheltered. According to Bradshaw: "The bay is open to the full south and southeast winds, and consequently well protected against all northerly winds. The Bora is not felt here. Northwest and northeast winds are tolerably frequent, though the latter are objectionable only as being cold. The atmosphere is never stagnant, owing to a sea-breeze which blows up to three o'clock, after which the land-breeze sets in. Rapid atmospheric disturbances, such as are met with on the Riviera, occur but seldom, and there is almost complete immunity from dust and high winds.

"The climate, though warm, is bracing. At the end of January and in February hyacinths, roses, and almond trees begin to blossom. By March, spring has set in, and in April cherries are ripening. The temperature rarely falls to freezing-point, and still more rarely below it. Fogs occasionally occur and last some time.

"The town itself offers many attractions. It is a link between the East and the West. Its streets are very lively. Close to the town on a small hill is a villa belonging to the King of Greece. The esplanade and the Strada Nuova are the centre of Corfu life. The environs are mostly covered with olive groves. The interior of the island offers a fine field for excursions and sports. Naples has been called the El Dorado of Hypochondriacs, and Corfu may claim the same honor. The drinking-water and the means of communication are excellent."

The class of cases sent to Corfu comprises many morbid states, and many tourists of the semi-invalid class spend more or less time there. Scrofula, chloro-anæmia, neurasthenia, protracted convalescence after severe ill-

ness, catarrhal affections of the upper air-passages, dyspepsia, gout, and incipient phthisis are all said to be benefited by a winter residence on this pretty island. There are fair hotel accommodations at moderate prices, postal and telegraph facilities, an English church, etc. The Hotel St. George is one of the principal establishments. *Edmund C. Wendt.*

CRANIAL AND SPINAL NERVES. The account of the development of the cranial and spinal nerves given in a previous volume of the HANDBOOK must now be considerably enlarged by reason of recent discoveries.

It is well known that the first trace of the nervous system is the formation, in the middle of the blastodermic area, of a longitudinal band of cells called the medullary plate; and that this plate, by the inversion of its edges caused by cell proliferation, is converted first into a groove, the medullary or neural groove, and afterward into a canal, the neural canal.

The epithelium forming the inner wall of the tube is, of course, derived from the ectoderm. Its cells show, even at an early stage when composed of but a single layer, a differentiation into two kinds that differ in shape, function, and subsequent history. One form, the spongioblast of His, is columnar, with oval nuclei, is passive in character, and constitutes the sustentacular portion of the tissue; the other, the germ-cell of His, is round, with a large nucleus which usually has karyokinetic figures indicating rapid proliferation, and is evidently more active in character. (See Fig. 123.)

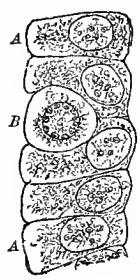

FIG. 123. — Ectoderm from the Medullary Plato of the Rabbit. *A, A*, supporting epithelial cells or spongioblasts; *B*, germ-cell. After His.

The cell-body of the spongioblast soon differentiates into two distinct substances, a clear, hyaloplasmic, non-stainable portion, probably of fluid consistency, and a dark, metaplasmic portion that is readily stained and becomes arranged in a reticular manner. This latter at first extends throughout the entire cell-body, but finally disappears at one end, and a columnar process is formed by the apposition of the walls of two contiguous cells, while at the other the basket-like reticulum remains. (See Fig. 124, *A*.)

At the ends of the columns the original boundaries of the cell remain defined by a ring of metaplasm, and a section parallel to the surface shows a flat sheet of lace-like net-work. (See Fig. 124, *B*.) Sooner or later the hyaloplasmic material disappears, leaving the nuclei with the columns stretching toward the free inner or ventricular surface of the medullary canal and the basket-work forming the external boundary of the original plate. (See Fig. 124, *C*.) This external boundary or reticulum becomes important, as it limits the migration of the active elements hereafter to be described. It is accordingly called by His the "border veil," for which Hill has proposed the equivalent term, *velum confine*.

By means of this arrangement of the spongioblasts there is laid down a trabecular framework with the trabeculæ disposed radially about the ventricular cavity of the neural tube. The system is termed the myelospongium, and is afterward developed into the neuroglia, which is, therefore, a purely ectodermic tissue correlative with the other nerve-elements, and not, as was formerly supposed, a mesodermic or true connective tissue. At an early stage the trabeculæ appear to anastomose. (See Fig. 125.) This is due to the adherence of the metaplasmic walls of contiguous cells.

Origin of Nerve-cells and Nerve-fibres.—Even when

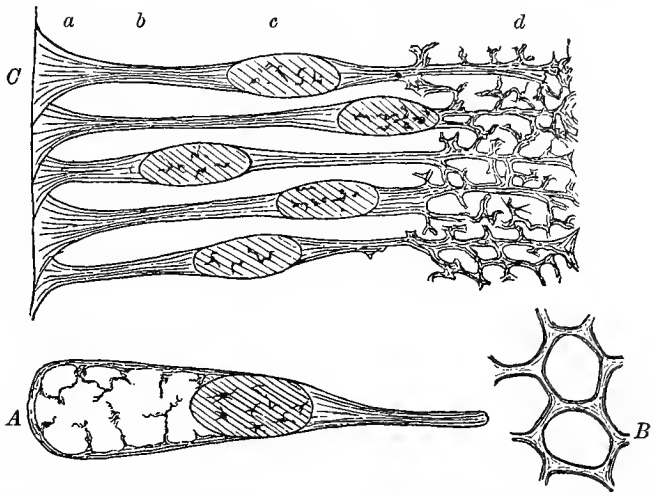

FIG. 124.—Details of the Spongioblasts. *A*, spongioblast in which the reticulum is forming at one end while the other has become columnar. *B*, arrangement of the inner ends of the spongioblasts to form the membrana limitans. the epithelium of the medullary plate is constituted by only a single layer, there are found here and there among the columnar cells the round-celled elements which have already been referred to as germ-cells. They occur in varying numbers, sometimes diffused at considerable intervals, sometimes quite closely packed. In the region of the neck they develop earlier than elsewhere. It is not yet known whether they develop from the spongioblasts, or exactly by what steps both are derived from the common, embryonic, ectodermal cells. They are found at first

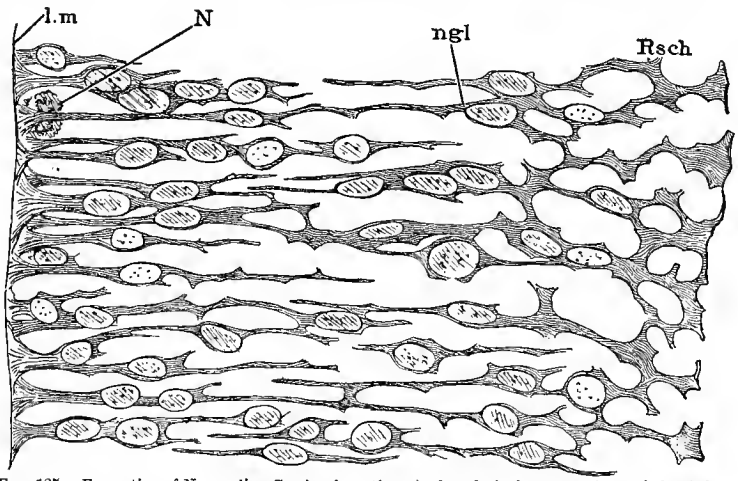

FIG. 125.—Formation of Neuroglia. Section from the spinal cord of a human embryo of about three and a half weeks. *l.m*, membrana limitans; *N*, germ-cell; *ngl*, neuroglia cells; *Rsch*, velum confine. After His.

in the so-called germinal area of the medullary tube, that is to say, quite near the ventricle or lumen of the tube, between the rod-like processes of the spongioblasts (see Fig. 126, *G*), or in rare cases extruding through the meshes of the membrana limitans and projecting into the ventricle.

Soon these cells begin to grow. At first spherical, they

become pointed and then pear-shaped, lengthening out into a conical process. They are then called *neuroblasts*, as they are the primitive nerve-cells, and the process is the beginning of a nerve-fibre. (See Fig. 126, *N*.) At this period they are evidently movable, as they migrate from the situation where first found, near the membrana limitans, and pass outward, following the radial interspaces of the spongioplasm, to become collected near the velum confine in a sheet, known as the mantle layer, which becomes the foundation of the gray matter of the cord. The

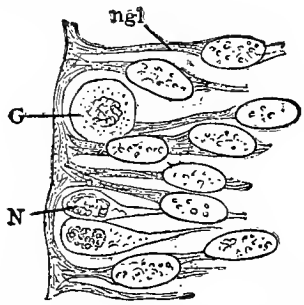

Fig. 126.—Development of Neuroblasts. From a section of the medulla oblongata of a human embryo. *G*, germ-cell; *N*, neuroblast; *ngl*, neuroglia cell. After His.

processes have now become striated and extend for a considerable distance peripherally. (See Fig. 127, *f*, *f'*.)

At the end of each growing process a slight enlargement occurs, and upon this there may be seen minute elevations or papillæ. The enlargement is called by Ramón y Cajal the cone of growth. The direction which these primitive fibres take differs somewhat in different regions of the cord. In the dorsal half the nerve processes turn so as to run vertically along the velum confine and parallel to the surface; in the ventral half they proceed directly outward, pierce the velum confine in compact bundles, and become the anterior or ventral roots of the spinal nerves. (See Fig. 128.)

The rounded head of the neuroblast usually undergoes

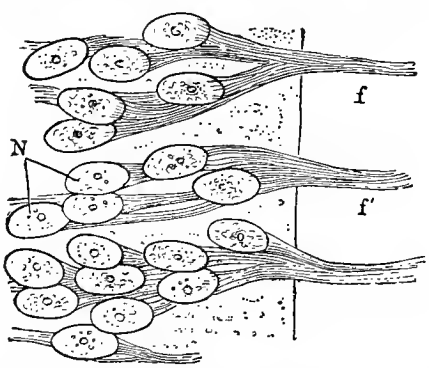

Fig. 127.—Neuroblasts forming Nerve-roots. Section from the spinal cord of an embryo cat. *N*, neuroblasts; *f*, *f'*, their processes combining in bundles to form the anterior roots of the spinal nerves. After His.

a further modification. Around its circumference small buds begin to appear which push outward in the same manner as the primitive process did, and develop into the so-called protoplasmic or dendritic processes of the nerve-cells. These are seen therefore to be of precisely the same character as the others, only differing in the time of their development. Lenhossék has shown, by observations upon the earthworm (Lumbricus), that there is originally no morphological difference between these processes. All the processes are dendritic in this animal, one set passing out to communicate with the periphery, another to convey impulses to other cells.

The primitive process which, because it assists in the formation of nerves, is now called the nerve process (axis cylinder process of Deiters), may, as already stated, pass out to become a constituent element of the anterior or

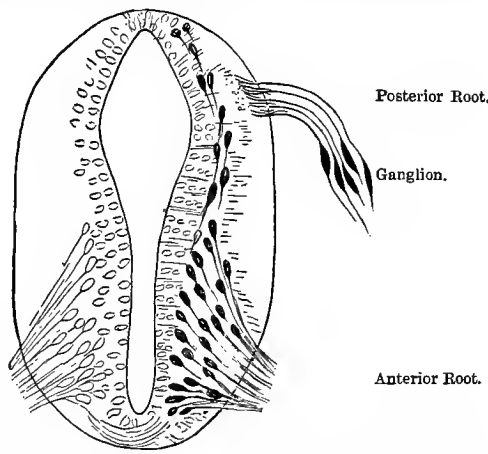

Fig. 128.—The Formation of the Nerve-roots. Section through the spinal cord of a human embryo. The condition of the anterior root corresponds to the development at the fourth week, that of the posterior to about four and a half weeks. Combined by Edinger from representations by His.

motor root of the spinal nerves. It passes to the periphery and there becomes associated with the muscular elements. Afterward the process becomes provided with a medullary sheath derived from the connective tissue of the mesoblast, the process itself being the axis cylinder of the nerve-fibre. Thus we see that we must no longer consider the fibres of the nervous system as elements distinct from the cells with which they are connected, but rather as integral parts of such cells. In the adult human body the cells of the anterior horn of the spinal cord send prolongations to the extremities of the

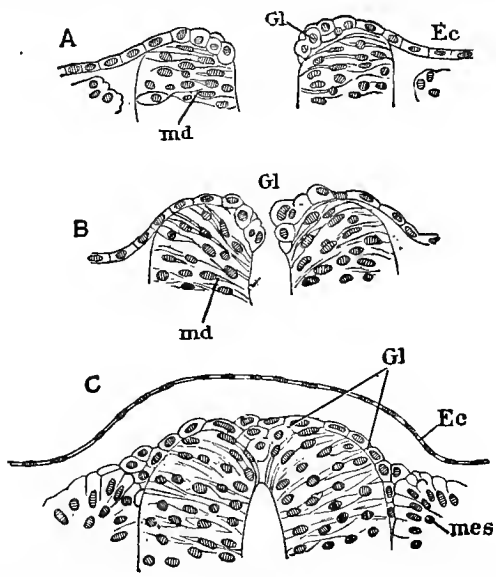

Fig. 129.—The Formation of the Neural Crest. Sections through the cervical region of a human embryo of 14 to 16 days. *Ec*, ectoderm; *mes*, mesoderm; *Gl*, beginning of the spinal ganglion, first known as the neural crest; *md*, medullary plate. After Lenhossék.

limbs. The growth of the nerve-process is at first quite rapid, but afterward decreases.

It seems at first difficult to understand how these processes can pass from the spinal cord and traverse so unerringly such a vast extent of the body (comparatively

speaking), and arrive at their destination in the group of muscle-cells to which they belong. Yet it should be remembered that the distance traversed is, at the stage of embryonic life at which this growth occurs, but a few centimetres at most; and further, it is noticed that the neuroblasts have a tendency to unite together in groups, sending out their processes together as a single bundle (see Fig. 127) which appears to be directed to a corresponding bundle of muscle-fibres, so that an exact adjustment of each neuroblast to a special myoblast does not appear to be necessary, the adjustment taking place rather between the grosser elements formed by the separate groups. It is not impossible that in this group-like arrangement of the primitive elements there may yet be found the key to a true morphological arrangement and classification of the muscles.

It will be noted that the foregoing account relates only to the origin of the anterior roots. The development of the posterior roots is no less instructive.

In Fig. 129 there are shown sections across the medul-

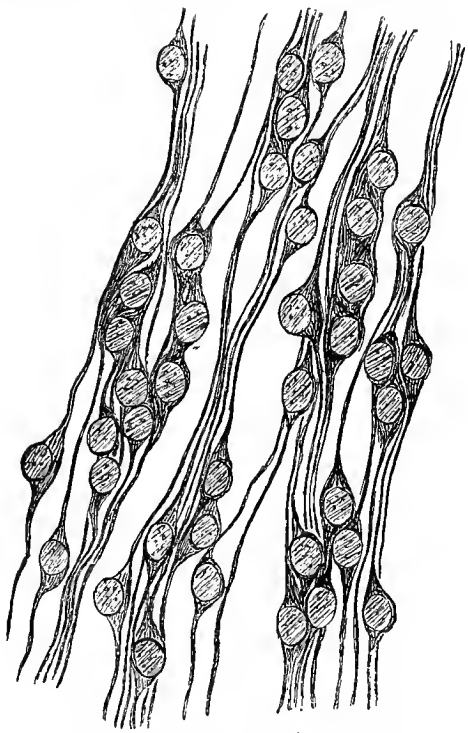

Fig. 130.—Gangliobiasts. Group of cells from the spinal ganglion of a human embryo. After His.

lary groove taken at different nerve-levels. At *A* the groove is widely open, the ectoderm exterior to it is seen as a thin layer which becomes thicker by the addition of some spherical cells, *Gl*, just at the edge of the groove. At *B* we see the groove nearly closed, and at *C* the closure completed. The spherical cells have united on the middle line to form a longitudinal band known as the neural crest. This at first occupies a median position and shares the segmentation which, though but slightly shown in the cord, is well marked in all accessories belonging to the nerves. It then becomes displaced on either side to form the ganglia situated on the posterior roots of the spinal nerves. It will thus be seen that the spinal ganglia are not, as they seem, integral parts of the nerves exterior to the cord, but detached portions of the original medullary plate, and should be regarded as displaced segments of the spinal cord. Therefore their cellular elements may well be of the same general nature.

This is found to be actually the case. The rounded cells of the neural crest assume a spindle shape before they become detached from the medullary canal. They are then termed gangliobiasts (Lenhossék). The ends of the spindle finally lengthen out into processes running in opposite directions, and a bipolar cell results. (See Fig. 130, also *A* of Fig. 132.)

In these cells the oval nucleus is placed to one side, so that the fibres run directly through opposite to each

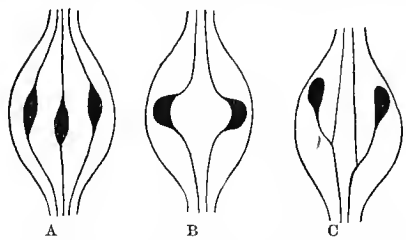

Fig. 131.—The Stages of Unipolarization of Ganglion Cells. (Lenhossék.) *A*, oppositipolar cells; *B*, geminipolar cells; *C*, unipolar cells.

other. The cells have accordingly been termed *oppositipolar* (Courvoisier). They resemble greatly at this stage the cells found in the ganglia of most adult fishes. The condition remains permanent in man only upon the ganglia connected with the auditory nerve, viz., the ganglion of Scarpa, found upon the vestibular nerve within the internal auditory meatus, near its origin from the auditory, and the ganglion spirale, found upon the cochlear nerve within the walls of the cochlea. In other situations the processes change their relations to the cell-body, for the axis of the ganglion being more and more invaded by nerve-fibres, the cells are pushed to the sides and the processes are so displaced as to be given off close together from one side of the cell, which is then called *geminipolar*. Finally the processes unite to form a single one, and the cell is then *unipolar*, the cell-body standing at some distance from an apparently continuous fibre attached as by a pedicle. The stages of the process are shown in the annexed diagram, Fig. 131.

It seems unlikely that this modification in the arrangement of the processes of the cell should make any material difference in its functions. The evidence that we have in regard to the functions of cells shows that the principal seat of activity is in the central protoplasmic mass, and especially in the nucleus of that mass. It seems, therefore, almost certain that the influences received from the periphery must travel up to the body of a unipolar cell, and thence out again toward the cord.

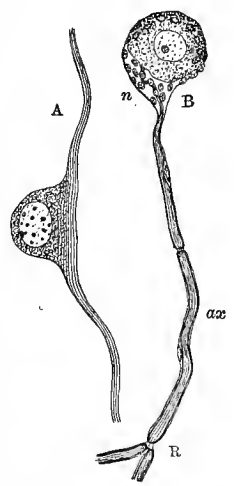

Fig. 132.—Cells from Spinal Ganglion. A. from human embryo of four and a half weeks; B, from an adult rabbit; *ax*, axis cylinder; *n*, nuclei of the medullary sheath; R, node of Ranvier. After His and Schiefferdecker.

The appearance of the adult ganglion-cell is shown in Fig. 132, B, where it is contrasted with the earlier form. The bifurcating fibres characteristic of these cells are known as the T fibres of Ranvier.

From a morphological point of view gangliobiasts may be regarded as cells of special sense, formerly situated at the periphery of the body, and now withdrawn to the edges of the medullary plate. In invertebrate animals, as, for example, in lumbricus (Lenhossék), such cells exist at the periphery and receive impulses like other sensory cells upon special collecting processes situated immediately under the epidermis. These impulses they transmit to the central nervous system by means of a

fibre. Such cells agree in general form with those of the anterior horn of the spinal cord, the collecting processes of the one corresponding to the dendritic processes of the other. When the cells are withdrawn to a more central situation, the connection with the collecting processes is made by a lengthened, secondary fibre, which becomes the peripheral pole of a bipolar cell. Other matters connected with the development of the ganglia of the cranial nerves tend to show that the ganglia may properly be considered as sense organs that have been withdrawn from the surface.

Thus it is found that both the anterior and posterior nerve-roots are formed of processes of cells situated, for the anterior roots, within the gray matter of the spinal cord, for the posterior roots, within the spinal ganglia.

This discovery is due almost entirely to the researches of His. It strikingly confirms the results obtained by section of the nerve-roots. It is well known that if the anterior root is cut the nerve-fibres degenerate from the section toward the periphery of the body, and that if the posterior root is cut between the ganglion and the cord the fibres do not degenerate, while if cut beyond the ganglion the fibres affected are speedily destroyed. (See Fig. 133.)

This was formerly ascribed to a supposed "trophic influence" which was thought to reside in the anterior horn of the spinal cord for the anterior roots, and in the spinal ganglion for the posterior roots. Since it is recognized that we are merely cutting off cell-processes, the results become intelligible.

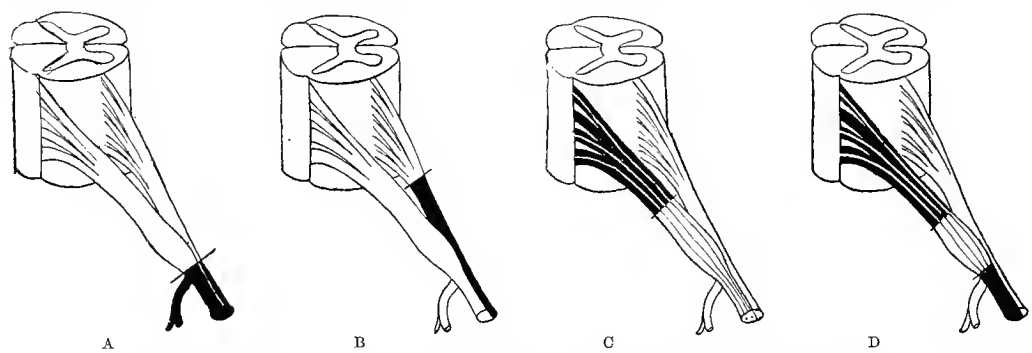

FIG. 133.—Degeneration of Nerve-fibres after Section. A, section of entire trunk beyond ganglion; B, section of anterior root; C, section of posterior root (a few fibres are shown as degenerating beyond the section); D, excision of ganglion.

Central Connections of Cells and Fibres.—The investigation of the central organs has long been singularly unsatisfactory from an anatomical point of view. The ganglion-cells in the spinal cord were first discovered by Ehrenberg in 1833, and described by Valentin in 1836. Those in the brain were discovered by Purkinje in 1838. In the same year Remak noticed that some processes of cells in the sympathetic nervous system appeared to be continuous with medullated nerve-fibres. Kölliker first noticed that such fibres arise from the unipolar cells of spinal ganglia. That these cells are usually bipolar in fishes was noticed in 1847 by several observers, independently, viz., Bidder and Reichert, Charles Robin, and R. Wagner. In 1851 Wagner, in examining the electrical organ of the torpedo, noticed that but one, or at most two, of the processes of the nerve-cells were connected with nerve-fibres. This was verified by Remak in the spinal cord of the ox in 1854. Special attention to these facts was, however, first drawn by Deiters in 1865, who noted that the greater number of the processes of the nerve-cells are short and break up immediately into fine arborescent forms that he called "protoplasmic" processes, but that among the others there was frequently found one that appeared to run without division. This he assumed to be continuous with the axis cylinder of a nerve-fibre, and therefore called it the axis-cylinder process. Recent discoveries have made it advisable to change these names. The first class are now known as dendritic processes, the second as nerve-processes.

Gerlach, in his excellent article on the spinal cord, published in Stricker's "Handbook of Histology" (1871–72), attempted to show that all cells are not provided with nerve-processes, that those so characterized are typically represented in the anterior horn of the spinal cord, and are probably motor, as they appear to be connected with the motor roots of the nerves, that the cells not so characterized are found in large numbers in the posterior horn of the spinal cord, and that their dendritic processes are united together to form a fine reticulum with which he believed the posterior roots to connect. This, therefore, was characteristic of the sensory nerves. Gerlach's views have prevailed until quite recent times, his "reticular formation" being mentioned as an anatomical fact in text-books now in general use, as for instance, Macalister's "Human Anatomy," 1889, and in Obersteiner's "Anatomy of the Central Nervous Organs," translated by Hill, 1890.

It is not at all surprising that those views should be held when the technical methods in use are considered. Every advance in histology has been heralded by some improvement in microscopic or in technical manipulation, and it is not always realized that our knowledge of minute anatomy is so recent. Schwann's researches on cells were not published until 1839, it was not until 1842 that Stilling invented the method of cutting thin sections in series, Gerlach first stained tissues in 1858. The wide extension of this method is now well known.

The preparations by which Gerlach sustained his views were prepared with the greatest care and are marvels of patient skill. He admitted, however, that he had never been able to trace a nerve-process into a nerve-fibre, nor had he actually demonstrated the connection of nerve-fibres with the plexus of dendritic processes. The connections of the fibres rested therefore upon hypothesis rather than upon any actual anatomical demonstration. The special obstacle in the way of progress was the great complexity of the interlacing fibres and processes that made it absolutely impossible to follow the connections of the cells for any distance. It seemed of no use to further pursue the subject by this method.

This being the case, attempts were made to obtain further knowledge of the connections of the cells by their behavior under pathological and embryological conditions. Waller, in 1852, discovered that when a nerve was cut its peripheral end degenerated. It was soon surmised that this same law governed certain degenerations found in lesions of the spinal cord and other portions of the central nervous system; and since the researches of His it is definitely known that degeneration occurs along the entire course of a nerve-fibre when it is severed from the cell from which it originally grew. Ample illustration of this is shown in Fig. 133. Since degenerated fibres can be readily distinguished in serial sections, it became possible to investigate the course of fibres or groups of

fibres by means of experimental lesions made in different portions of the spinal cord.

By observing degenerations, whether artificially produced or the result of pathological processes, it was soon found that the central connections of the cranial and spinal nerves were not arbitrarily arranged, but that they followed a certain definite plan. A knowledge of this was often assisted by the study of malformations in which special tracts of the central nervous system were found to be wanting.

Another discovery also greatly aided investigation. In the early embryo the only nerve-fibres found are those of the non-medullated variety, the myelin being afterward added. Flechsig (1872–76) found that this process of myelination does not occur at the same time in all parts of the nervous system, but seems to follow certain definite laws. Certain of the tracts already made out by the study of degenerations were found to myelinate at a different period from others, and thus their connections could be made out, confirming and amplifying the data already obtained.

It would be beyond the scope of this article to give a complete account of the researches made under these different heads. It will be necessary, however, to give a short summary of the principal results obtained with regard to the central connections of the cranial and spinal nerves at the date of the publication of the HANDBOOK in order to make intelligible the recent discoveries. (See Fig. 134.)

In the gray matter of the cord certain rather ill-defined clusters of cells were made out which were thought to have certain definite relations to the nerve-roots. The anterior or motor root was composed of fibres arising from cells in the anterior and lateral horns. Those in the anterior horns are in three groups, described by Waldeyer as the antero-medial, antero-lateral, and postero-medial. The large cells of the lateral horn are considered by themselves and termed by Waldeyer the postero-lateral group. The postero-medial group was believed not to send fibres to the root of the same side, but to communicate through the anterior gray commissure with the anterior root of the opposite side.

The fibres of the posterior root were not considered to be connected with cells, but rather with the plexus of Gerlach. An exception was made, however, with regard to certain cells found in the column of Clarke, each of which was believed to have two processes, by one of which it was connected with the fibres of the posterior column. It was, however, acknowledged that many of the fibres of the posterior root did not enter the plexus at all: some turned inward and upward passing toward the brain, first in the column of Burdach, then in the column of Goll; others passed into the lateral column where their subsequent course was unknown.

The idea generally prevailed that the transmission of nervous impulses could only be explained by assuming a continuity of structure. The fibres and the cells must be continuous with other fibres and cells in order to produce the so-called nerve-paths by which these impulses travelled. Thus the ordinary reflex acts which physiologists found to occur within the spinal cord were believed to be produced by the transmission of sensations through the posterior roots to the plexus of Gerlach, from which they were transferred either to a motor cell or to nerve-fibres formed by the union of the fibrillæ of the plexus. The act was thus made clear and intelligible. It did not, however, rest upon any actual demonstration.

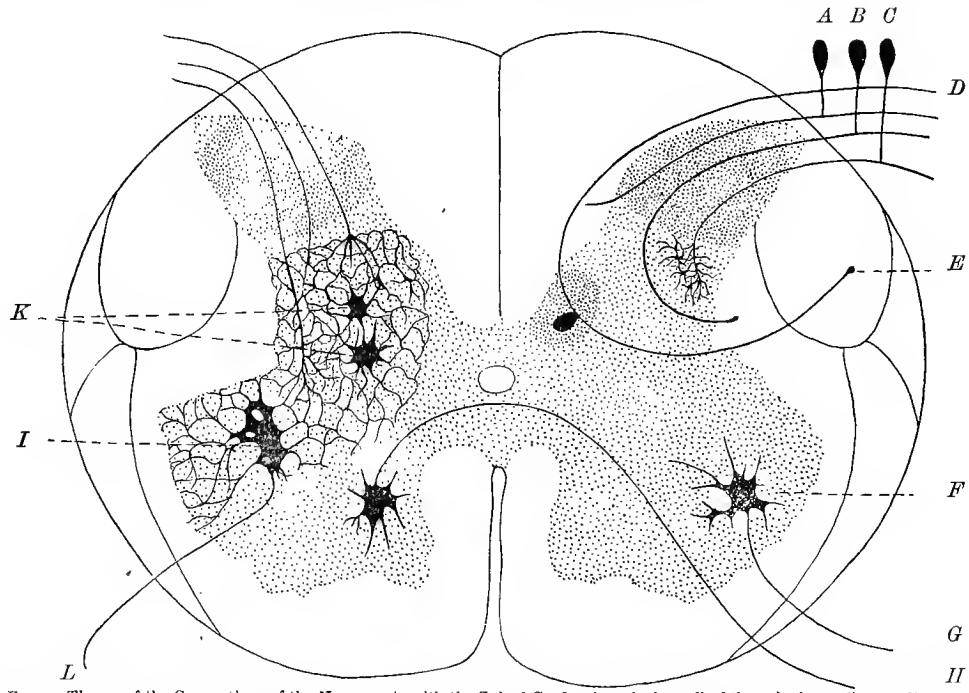

FIG. 134.—Former Theory of the Connections of the Nerve-roots with the Spinal Cord. A, unipolar cell of the spinal ganglion sending process to the column of Burdach; B, same sending process to lateral column; C, same ending in Gerlach's plexus of the posterior horn; D, fibre of posterior root passing to a bipolar cell in the column of Clarke; E, the other process of the same cell passing to the cerebellar lateral tract; F, large motor cell of the anterior horn ending in a nerve-process G, that passes into the anterior root; H, nerve-process from a cell of the anterior horn of the other side of the cord that passes through the anterior gray commissure; I, K, cells that form the plexus of Gerlach by anastomoses of their dendritic processes; L, nerve-process from one of these cells passing to the anterior root.

A short notice should be given to the views which have been advanced by Gaskell upon the nature of cranial and spinal nerves.

On section of a nerve stained with osmic acid, it is noticed that the fibres involved are by no means all of the same calibre, or provided with the same thickness of medullary sheath. Nerves that supply the voluntary muscles appear to have a large proportion of large, dark-bordered fibres, while those supplying involuntary muscles and viscera have a great majority of small, fine me-

dullated, or so-called "leucenteric" fibres. (See Fig. 135.)

Gaskell showed that these leucenteric fibres pass out of the spinal cord at certain definite levels, corresponding to

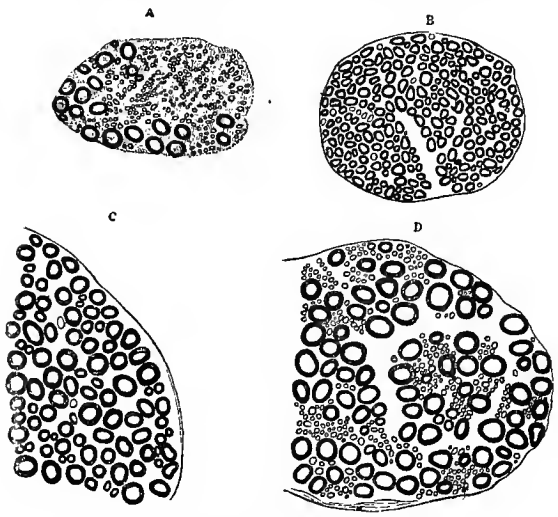

FIG. 135. — Sections across Parts of the Roots of Various Nerves of the Dog, to show the Variations in Size of their Constituent Fibres (Gaskell). The nerves were stained with osmic acid and the sections are all drawn to one scale. *A*, from one of the upper roots of the spinal accessory; *B*, a rootlet of the hypoglossal; *C*, from the first cervical anterior root; *D*, from the second thoracic anterior root.

the exit of the fibres going to the splanchnic nerves and other trunks of the sympathetic nervous system. He thus divided the nerve-fibres into two classes, the *somatic*, supplying the somatopleuric portion of the mesoderm, and the *splanchnic*, supplying the splanchnopleuric portion. These he again separates into efferent and afferent subdivisions.

He also assigned to certain definite cell-groups in the spinal cord the function of presiding over these separate nerve-fibres. The somatic efferent nerves he connected with the large cells of the anterior horn; the splanchnic efferent with those of Clarke's column; the cells of the lateral horn with the solitary cells at the base of the posterior horn.

No special groups for cells are assigned to the efferent nerves.

He considers that in the system of cranial nerves certain of these groups have a tendency to break up and form special nerve-strands. His application of the theory will be seen on examining Figs. 137 and 138.

To an Italian anatomist, Camillo Golgi, of Pavia, is due the discovery of methods of staining nerve-fibres which has led to most important practical advances in our knowledge. This is essentially an impregnation of the tissue with either a chromic salt or bichloride of mercury, and then placing it in a silver solution. After suitable maceration in this it is found that a fine deposit occurs along every nerve-fibril, distinctly marking it out. This deposit is probably a chromate or chloride of silver precipitated in exceedingly delicate crystals. The preparation of material by this method is by no means easy. It must be perfectly fresh; the solution must be of a certain definite strength; the exposure is long, weeks and even months being required for some results, and certain precautions in handling and keeping are absolutely necessary. The section must be mounted in Canada balsam without a cover glass.

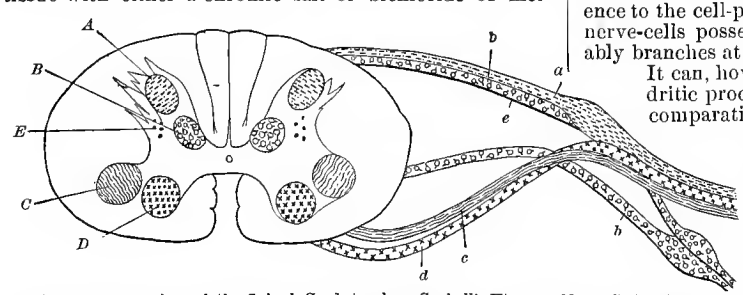

FIG. 136.—Cross-section of the Spinal Cord, to show Gaskell's Views. (Hans Gadow.) *A*, cells of posterior horn; *B*, cells of Clarke's column; *C*, cells of the lateral horn; *D*, cells of anterior horn; *E*, solitary cells at base of posterior horn; *a*, somatic afferent fibres; *b*, splanchnic ganglionated efferent fibres; c, splanchnic non-ganglionated efferent fibres for visceral and enteric muscles; *d*, somatic efferent fibres; *e*, splanchnic afferent fibres.

The results obtained are truly astonishing. For the first time every detail of the cell-processes is clearly made out, marked with the precision of a line of black upon a white page. It is no longer necessary to deal with nerve-cells that have been mutilated and displaced from their natural connections by teasing, their processes appearing

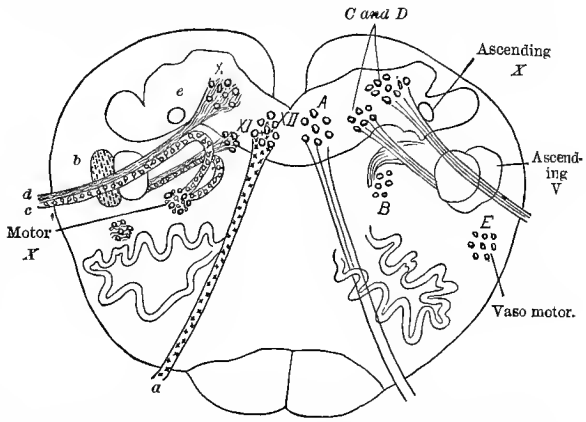

FIG. 137.—Schematic Cross-section of the Medulla Oblongata. (Gaskell.) *A*, cells corresponding to those of anterior horn; *B*, cells corresponding to those of lateral group of anterior horn; *C*, cells corresponding to Clarke's column; *D*, cells corresponding to the solitary cells at base of posterior horn; *E*, cells corresponding to those of lateral horn; *a*, somatic efferent fibres; *b*, somatic afferent fibres; *c*, splanchnic non-ganglionic efferent fibres; *d*, splanchnic ganglionated efferent fibres; *e*, splanchnic afferent fibres.

as bare stumps, and all fine details of structure swept away. Another advantage is that, for some reason not yet clearly understood, certain cells of the section stain sooner than others, so that by adjusting the time of maceration it is possible to obtain only a few cells stained at a time, and thus to follow out the complicated ramifications of a single cell without having it confused by the details of the other cells in its immediate neighborhood. By varying the procedure slightly it is possible to stain the neuroglia without affecting the other elements.

Golgi was at once able to settle definitely certain important matters. The connections of the nerve-roots became no longer matters of surmise and hypothesis, but reached the realm of actual ocular demonstration. He was able to show that the prevalent theory with reference to the cell-processes was incorrect. Not only do all nerve-cells possess a nerve-process—that process invariably branches at a greater or less distance from the cell. It can, however, be distinguished from the dendritic processes by its manner of branching and its comparatively simple course.

There exist two types of cells, distinguished by the behavior of their nerve-processes: First, those in which the nerve-processes preserve their integrity for a considerable distance, always giving off, however, some collaterals, passing finally into a nerve-fibre and breaking up at its termination; 2d, those in which the nerve-process after a short course divides and subdivides within the gray substance of the nervous centres, form-

ing thus the plexiform arrangement described by Gerlach. The nerve-processes of these cells never contribute to the formation of nerve-fibres. (See Fig. 139.)

Golgi was not able to fully disembarrass himself of the old ideas with regard to the anatomy of the nerve-centres. As the cells with long nerve-processes are found mostly within the anterior horn of the cord, he concluded that they must necessarily be motor cells. He also assumed that the great part of the cells of the second type, that is to say, those with short nerve-processes, were to be found in the posterior horn, and must therefore be considered as sensory cells. In fact, his view differed but very slightly from that of Gerlach, as will be seen by contrasting the two diagrams in Fig. 140. The difference was merely one which affected the processes by whose ramification the plexus was made up. While Gerlach assigned this *rôle* to the dendritic processes, Golgi considered that it was effected by the collateral branches of the nerve-processes, and that reflex phenomena take place through this plexus in essentially the same way as imagined by Gerlach, and that by its connections with other nerve-roots different levels of the cord are excited and associated for co-ordinate movements.

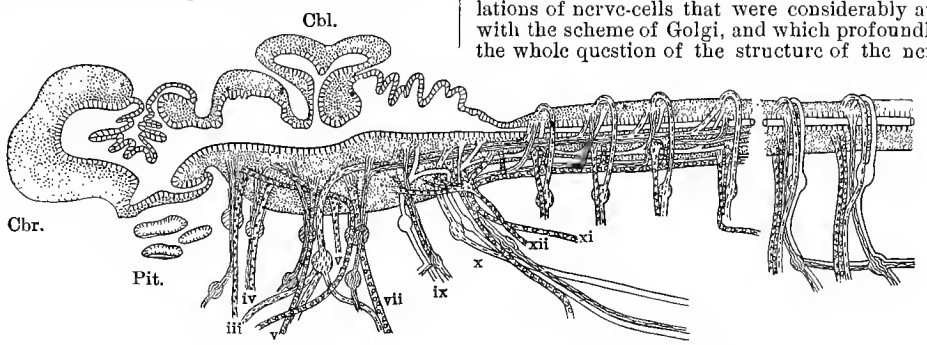

FIG. 138.—Diagram of the Arrangement of the Cranial Nerves. (Gaskell.)

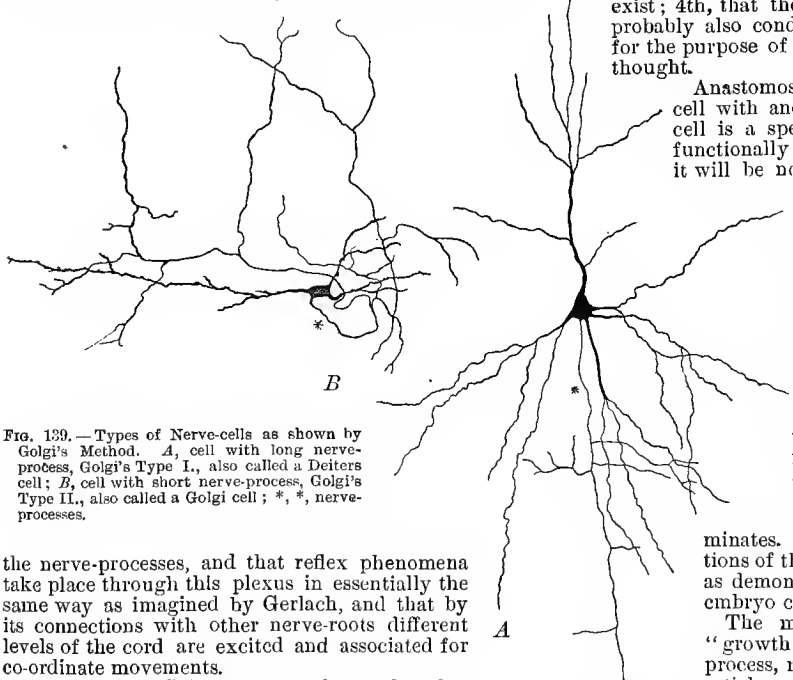

FIG. 139.—Types of Nerve-cells as shown by Golgi's Method. *A*, cell with long nerve-process, Golgi's Type I., also called a Deiters cell; *B*, cell with short nerve-process, Golgi's Type II., also called a Golgi cell; *, *, nerve-processes.

The method of Golgi was soon taken up by other histologists and applied to a wide range of research. It has been especially fruitful in the hands of the well-known Spanish investigator, Dr. Santiago Ramón y Cajal, Professor in the University of Barcelona. Great advantage is obtained by applying it to embryonic tissues, as the field is much smaller and the elements fewer, so that it is possible to bring an area corresponding to a considerable extent of the adult tissues within the limits of a single specimen. Then, too, it is found that the embryonic tissues are particularly susceptible to this method of investigation.

In studying by the new method the cerebellum of the embryo of birds and mammals, Ramón y Cajal arrived at certain conclusions with reference to the nature and relations of nerve-cells that were considerably at variance with the scheme of Golgi, and which profoundly affected the whole question of the structure of the nervous system. Continuing his observations to the investigation of the spinal cord, he was able to show, first, that the nerve-cells are entirely independent, and never anastomose either by their dendritic or by their nerve-processes; 2d, that every nerve-process, whether long or short, ends either simply or by ramifications which may either be within the motorial end-plate of a muscle-fibre, as in the cells of Golgi's type I., or in protoplasmic expansions in contact with the body or processes of other cells; 3d, that these latter establish by contact alone communications as effectual for the transmission of impulses as the continuity of structure formerly supposed to exist; 4th, that the dendritic processes of cells are probably also conducting elements, and not merely for the purpose of imbibing nutriment, as heretofore thought.

Anastomosis of the processes of one nerve-cell with another is absolutely denied. Each cell is a special structural unit that remains functionally and anatomically distinct. This, it will be noted, agrees entirely with the embryological evidence produced by His; for each cell, with its dendritic and nerve-processes extending perhaps a distance of several feet, is the result of the growth of a single neuroblast. Waldeyer has given to each of the units so formed the name of *neuron*. The entire nervous system is a combination of neurons, independent in structure, and combined for functional purposes by the juxtaposition of their processes. Each neuron may be considered as composed of three portions: the cell-body, the nerve-fibre, and the fibrillary arborescence in which the fibre terminates. The appearance of the connections of the nerve-roots with the spinal cord, as demonstrated by Golgi's method in the embryo chick, is shown in Fig. 141.

The minute elevations noted on the "growth cone" at the end of each growing process, referred to in the first part of this article, are apparently the budding terminal fibrillæ of the fully developed neuron. The power of peripheral extension appears by no means to be confined to fœtal life. It is probably by such extension, from already existing cells and fibres, that nerves are renewed after section. There appears indeed to be a general tendency for fibres to extend until arrested at the periphery. When cut, as in amputations, they still continue to grow, causing the well-known convoluted growths (traumatic

neuromata) found in stumps after healing, His suggests that it is by a similar extension of growth of fibres within the central organs that one portion of the brain is enabled to assume vicariously the functions ordinarily belonging to another part, after such part has been destroyed or become disabled. The growth of fibres is by no means

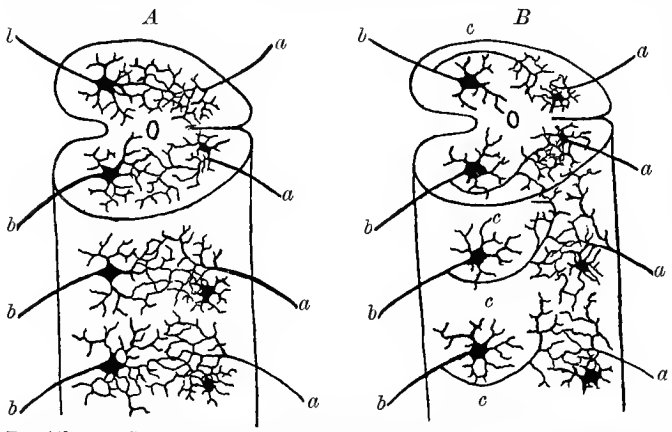

FIG. 140.—The Connection of the Nerve-roots in the Spinal Cord. (Van Gehuchten.) *A*, Gerlach's view; *B*, Golgi's view: *aa*, posterior roots; *bb*, anterior roots; *cc*, collaterals of the nerve-processes of the anterior roots.

rapid—weeks and even months being required for them to reach their ultimate destination.

The cells belonging to the spinal ganglia, in some cases, end peripherally without bifurcation, and become enveloped by special sheaths of connective tissue, as in the corpuscles of Pacini or of Krause; in others they divide into fibrillæ that end freely in the intercellular spaces.

What, now, are the central connections of the fibres derived from the posterior roots? Already, in 1885, Nansen had demonstrated that in *Myxine glutinosa*, one of the lowest fishes, those fibres bifurcate upon reaching the white substance of the cord. Golgi also had seen such

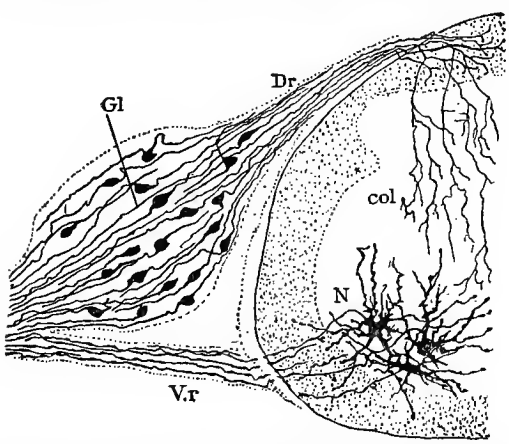

FIG. 141.—Transverse Section of the Spinal Cord of a Chick at the Ninth Day of Incubation. (Ramón y Cajal.) *V.r*, axis cylinders of anterior root-fibres issuing from the large cells of the anterior horn, *N*; *Dr*, posterior root-fibres passing from the bipolar ganglioblasts of the spinal ganglion, *Gl*, into the posterior column of the spinal cord, where they bifurcate and send collaterals that penetrate the gray matter.

bifurcations, as appears from publications made by him in 1881. These observations were, however, fragmentary and without special result. It was reserved for Ramón y Cajal to clearly unravel the central connections. His first publications were received with the same incredulity as those of his predecessors, and the text-books of Obersteiner, Edinger, and others, on the anatomy of the nervous centres, although published some time after his discoveries had been made, yet give no account of them. But in 1889, at the meeting of the Anatomical Society at Berlin, he exhibited specimens which convinced the most sceptical. The discoveries were immediately taken up and fully confirmed by von Kölliker, of Würzburg; Waldeyer, of Berlin; Lenhossék, of Basel; and van Gehuchten, of Louvain; all of whom have published important papers on the subject.

The fibres of the posterior root, according to these observers, are of two varieties, centripetal and centrifugal. The former, by far in the majority, do not enter the gray substance as undivided fibres, according to the prevalent view, but immediately bifurcate, Y-like, one limb ascending, another descending. These limbs run longitudinally in the posterior columns of the cord, which are almost wholly made up of these continuations of the posterior roots. (See Fig. 142.)

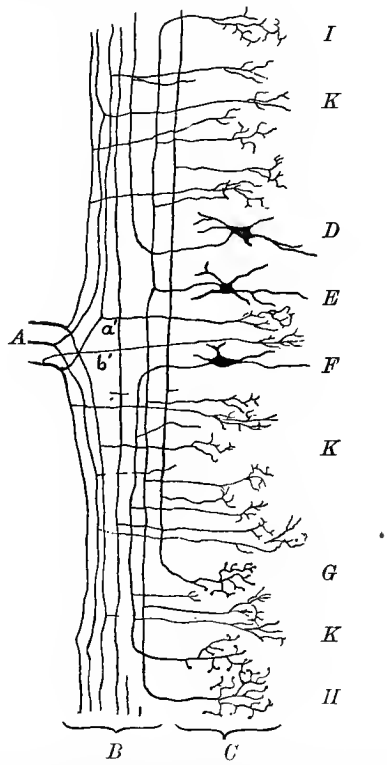

FIG. 142.—Entrance of the Posterior Roots of the Spinal Nerves. (Ramón y Cajal.) A semi-diagrammatic, longitudinal section of the posterior column of the cord, taken parallel to the entrance of the posterior nerve-roots. *A*, posterior root; *B*, white substance; *C*, gray substance; *D*, cell of the posterior horn whose nerve-process bends upward; *E*, cell with bifurcating nerve-process; *F*, cell whose nerve-process bends downward; *G*, *H*, and *I*, final ramifications of nerve-processes; *K*, *K*, *K*, final ramifications of collaterals; *a'*, collateral from the ascending branch of a nerve-fibre of the posterior root; *b'*, collateral from the main trunk of a fibre of the posterior root.

These latter fibres give off, at right angles to their course, delicate collateral branches (*a'*, Fig. 142) which penetrate the gray substance and terminate by free ramifications (*K*) that surround the nerve-cells. Collaterals may also be given off from the trunk-fibre before its division (*b'*). A slight thickening is observed at the point where these collaterals arise, and their origin is always, as in the division of the single pole of an adult ganglioblast (Fig. 132, *B*), at a node of Ranvier.

The ascending and descending limbs of the bifurcating fibre probably end by bending sharply at a right angle, taking a course like the collaterals, and breaking up in a similar manner. Their full extent has not been completely demonstrated. In the embryo the course of the fibres has been followed for a distance of several milli-

metres, and it has been estimated by Kölliker that this corresponds to a distance of from six to seven centimetres in the adult. From clinical and experimental evidence it is believed that they extend much further. It is known that after section of the posterior roots an ascending degeneration occurs, reaching as far as the medulla oblongata to the nuclei found in the columns of Goll and Burdach, or perhaps even higher. Also, that a certain amount of descending degeneration occurs, not extending, it would appear, for any very great distance.

As the fibres of each successive nerve-root divide, the ascending and descending limbs push those coming up from a lower level toward the middle line, so that their ascending course is slightly oblique rather than vertical, and at last they are displaced from the column of Burdach to the column of Goll. This accounts for the fact already noted by physiologists, that lesions of the latter column are usually found to be associated with the leg rather than the arm; and also explains the reason why that column is usually composed of finer fibres. Containing the terminals of the fibres that enter on much lower levels than those in the column of Burdach, they would naturally be smaller. The fibres of the column of Goll also acquire their myelin sheaths at a later date. (Flechsig.)

The course and ultimate distribution of the collaterals within the gray matter of the cord is, it will be seen, of considerable interest, as it may be expected

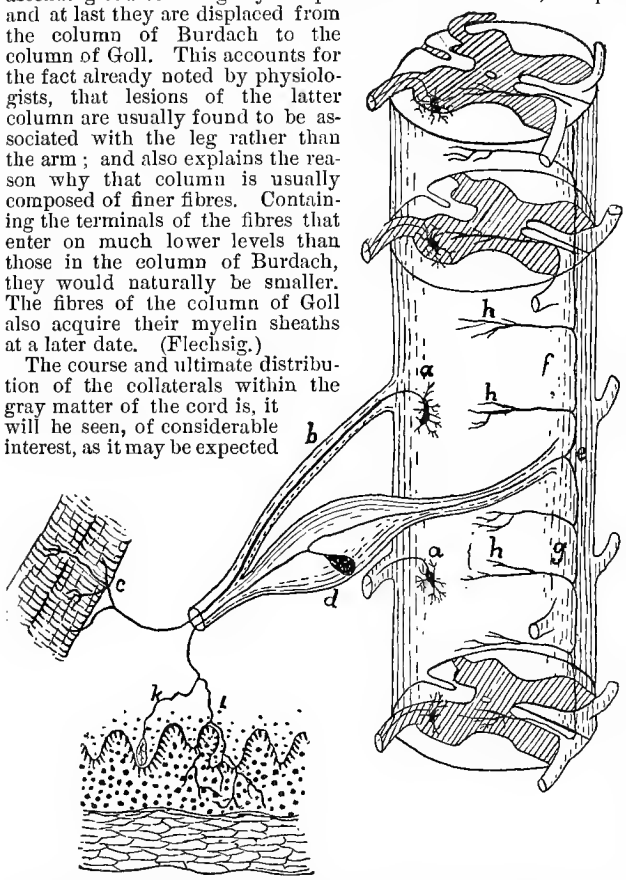

FIG. 143.—Scheme of Simple Reflex Action. (Lenhossék.) *A*, motor cell of anterior horn; *b*, its nerve-process extending through the anterior root; *c*, its termination by ramifications upon striped muscular fibres; *d*, a single ganglioblast situated in the ganglion of a posterior root and sending into the cord a centripetal fibre that bifurcates at *e* into an ascending limb, *f*, and a descending limb, *g*; *h*, *h*, collaterals that reach by their ramifications the motor cells of the anterior horn; *i*, the peripheral origin of the other process of the ganglioblast from ramifications ending free in the epidermis; *k*, from a Pacinian corpuscle.

to throw light upon the physiological processes in which the cord takes part. We may divide them into several categories, as follows:

I. A large number of the collaterals belonging to the posterior roots unite in a bundle which crosses the posterior horn and breaks up into terminals that ramify about the cells of the anterior horn. (Fig. 144, 1.) There is thus established the reflex-path imagined by Gerlach and Golgi (see Fig. 140), there being, however, this difference in the new conception, 1st, that the path is not made directly by the fibres of the posterior roots, but by their collaterals; 2d, that the terminals do not anastomose with the cell-processes of the anterior horn.

On consulting Fig. 143, it will be seen that sensations taken up from the skin by the nerve-filaments *i* and *k*, are conveyed to the ganglioblast at *d*, and thence to the cord, where by the bifurcation at *e* they may extend either upward or downward, and affect different levels supplied by the collaterals *h*, *h*, *h*, which in their turn communicate by contact with the motor cells *a*, *a*, that convey impulses through the anterior root, and by terminal ramifications to the muscle-fibre *c*. It will be noticed that but two neurons are involved in this act.

II. Another bundle of collaterals passes to the column of Clarke from the middle region of Burdach's column. The fact that such a path existed was already demonstrated by Flechsig ("Leitungsbahnen," Plate xviii., Fig. 123), as shown on Fig. 134, D. The fibres break up within the column, surrounding the cells with a rich net-work. The fibres are provided with a medullary sheath much farther than usual, and this is thought to be the reason why Clarke's column has such a markedly fibrous appearance when colored by hæmatoxylin (Lenhossék), and why it is one of the first areas to show degeneration in tabes.

III. A few collaterals pass from the fibres of the posterior root through the gray posterior commissure, to break up into tufts in the posterior horn of the opposite side, in front of the substantia gelatinosa of Rolando. (Fig. 144, 3.) Unilateral section of the cord, as is well known, abolishes tactile sensation on the opposite side below the lesion. The decussating fibres here described are, however, evidently insufficient to fully account for this phenomenon. These decussating fibres are much more marked in the dog, rabbit, and guinea-pig than in man.

IV. A great number of the collaterals from the fibres of the posterior root penetrate the posterior horn, passing through the substantia gelatinosa and breaking up in the gray matter immediately beyond. These are the fibres that have been hitherto noticed by anatomists streaming through the gelatinous substance in arcades like meridians of longitude on the surface of the globe. The terminal filaments are unusually fine and numerous, and being readily stained, produce the appearance which Waldeyer has called the nucleus of the posterior horn.

As to the elements of the posterior nerve-roots which have been spoken of as centrifugal, it is noticed that when the roots are cut a small number of fibres degenerate peripherally. (See Fig. 133.) These have no connection with the cells of the spinal ganglia. Lenhossék thinks that in the spinal cord of the chick, on the fifth day of incubation, he has been able to demonstrate that these fibres arise from cells in the anterior horn. Their function is unknown. If their existence in all vertebrates is ascertained, it will be a very interesting exception to the well-known law of Bell, by which the posterior roots are held to be exclusively centripetal.

It will be evident from this sketch of the behavior of the posterior roots, that an account of them will be incomplete without some notions of the cells of the cord with which they are anatomically related, and to which they probably transmit their impulses. Upon the right-hand side of Fig. 144, the principal groups of such cells are diagrammatically indicated.

Radicular Cells.—Those are the cells already referred to that send processes to the nerve-roots. (Fig. 144, *a*, *a*.) They are confined to the anterior and lateral portions of the anterior horn, and send their processes to the anterior root already adverted to. The passage of fibres from cells of one anterior horn to the anterior root of the opposite horn (Fig. 133, *h*) is positively denied by all recent observers.

Commissural Cells.—These are cells that send a nerve-process to the opposite side of the cord by the way of the anterior commissure. (Fig. 144, *c*, *d*.) Ramón y Cajal finds them distributed throughout the gray matter in all parts of the cord. Lenhossék describes a special group

of these cells on the medial side of the anterior horn, and these are the ones which were formerly supposed to send fibres to the anterior root of the opposite side. Commissural cells are usually smaller than the radicular cells, and their nerve-processes may spring either from the cell-body or from one of the dendritic trunks. The axis cylinder may (1) break up at its termination into the usual arborization; or (2) divide into two branches, one of which breaks up, the other proceeding to the adjacent white matter; or, (3) after bifurcating, both branches may pass to separate portions of the white matter. The branches proceeding to the white columns may either bend simply upward, or divide T-like, sending branches upward and downward. This affords an interesting anatomical explanation of the simultaneous ascending and descending degenerations sometimes found after lesions of the opposite side of the cord. Occasionally lateral branches may be seen given off from the nerve-process in its course.

It will be remembered that, in considering the distribution of the collaterals of the posterior nerve-roots, it was found that but a very small number penetrate to the opposite side of the cord, and that these were insufficient to explain the phenomena of crossed, tactile sensations. The discovery of the commissural cells makes the matter clear. They appear to constitute neurons of the second order, that serve to transmit to the opposite side of the cord impulses received from the periphery. It should also be noted in this connection that those fibres that ascend from the posterior roots in the columns of Goll and Burdach are interrupted, when they reach the medulla oblongata, by the nuclei found in those columns, and there transfer their impulses to neurons which decussate like the commissural cells of other levels of the cord. These nuclei then are in fact local collections of such commissural cells.

In a former volume of the HANDBOOK (VIII., p. 186) it was noted by Spitzka that it is probable that the lemniscus tract of the brain is composed of fibres that take up impulses from the nuclei of the posterior columns, and also communicate through the tegmental region with the cortex of the brain. After removing the parietal lobe of the cat, Monakow found that the lemniscus tract degenerated, and could be traced to the nucleus of Goll's column of the opposite side.

Column Cells (células de los cordones, Ramón y Cajal). —These pass from the gray substance into the surrounding columns of gray matter of the same side. (Fig. 144, *c*.) They are scattered without order in nearly all parts of the cord, but are especially abundant in the middle zone of the gray substance, that is to say, the region between the anterior and the posterior horns. They are usually of median or small size. They may either divide into ascending and descending branches, or simply turn up without division. Sometimes their nerve-processes divide within the gray matter and send two or even more divisions into the columns at a distance from each other, which divisions comport themselves like a single fibre (células multicordonales, Ramón y Cajal). Most of these cells send their processes to the anterior and lateral columns. These processes quite frequently show an increase of calibre during their course. Among the interesting cells of this class are those of the column of Clarke, whose processes pass outward and turn toward the brain in the cerebellar lateral tract. The existence of a path of this kind has been known since Gerlach and Flechsig, and it is sometimes called Flechsig's bundle. (See Fig. 134, *E*.) It has been hitherto supposed that the cells of the column of Clarke were many of them bipolar. (See Mott, Obersteiner, p. 182, and Fig. 107.) This is now shown to be an error. They are all multipolar cells with extremely rich dendritic processes. These are sometimes given off from two stems arising at opposite ends of the cell, and as the processes are for the most part torn away in the preparations ordinarily made, the cells then appear as bipolar.

The collaterals that were mentioned above as passing to the column of Clarke, surround these cells with an interlacing basket-work of processes. From clinical evidence it is believed that the impulses here conveyed are

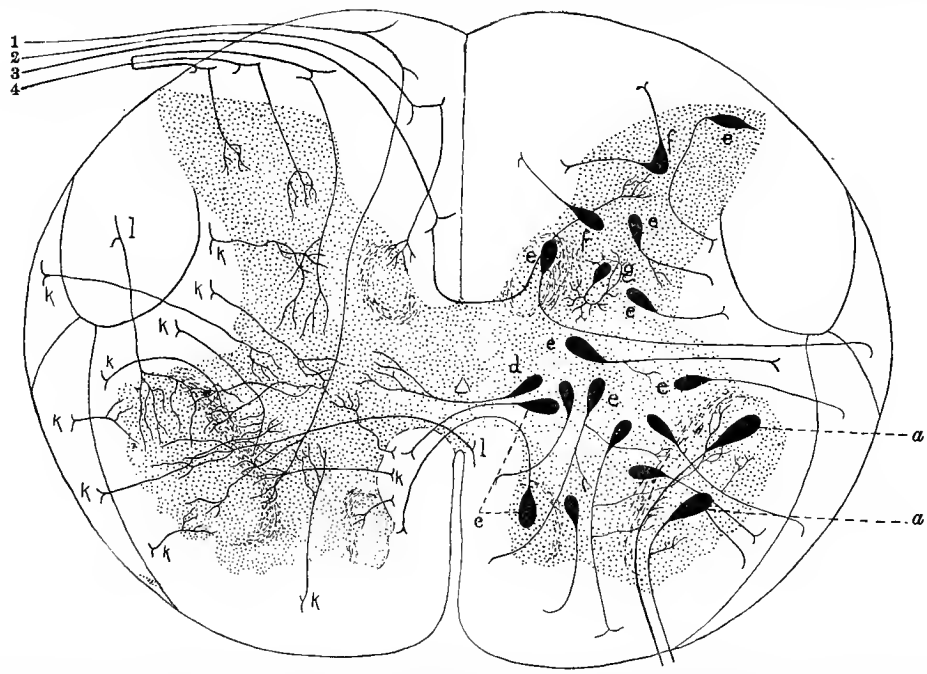

FIG. 144—Scheme of our Present Knowledge of the Relations of the Cells and Fibres of the Spinal Cord. (Lenhosšék.) The right side of the figure shows the cells of different classes found in the cord with their processes. The left side shows the processes of cells whose bodies are either beyond the cord or at other levels, with the distribution of their collaterals. *a, a*, Motor cells of anterior horn; *c*, commissural cells; *d*, Golgi commissural cell; *e, e*, columnar cells of antero-lateral column; *f, f*, columnar cells of posterior column; *g*, Golgi cell of posterior horn; 1, fibres of posterior root forming the antero-posterior reflex tract; 2, fibres passing to column of Clarke; 3, commissural fibres of posterior root; 4, fibres that enter the posterior horn; *k, k*, collaterals of antero-posterior column; *l, l*, collaterals from the pyramidal tracts.

not those that relate to tactile sensation, but rather those which concern co-ordination of movements. The cells constitute neurons of the second order, communicating with the cerebellum. It is well known that disorders of the cerebellum produce inco-ordination of movements, and also that when a sclerosis is set up about the cells of Clarke's column and the elements atrophy, as in tabes dorsalis, that inco-ordination is one of the prominent symptoms. There is no ground for the hypothesis advanced by Bechterew, that these cells communicate with the column of Goll.

But few cells are found that send nerve-processes into the posterior columns. Lenhossék has found some such in the posterior horn behind the column of Clarke.

Cells occupying the area of the posterior horn known as the substantia gelatinosa of Rolando, send their processes for the greater part to the area at the tip of the posterior horn, which, since Lissauer's description, has been known as the zona terminalis. The cells of the substantia are large and spindle-shaped, and were formerly

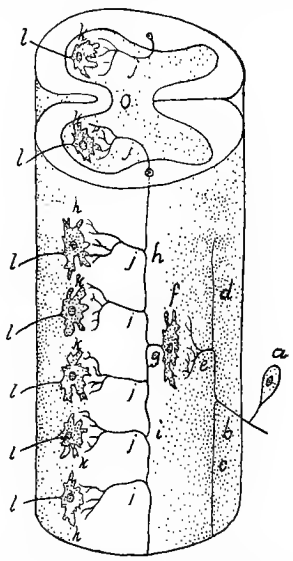

Fig. 145.—The Indirect Reflex Path. (A. v. Kölliker.) *a*, Gangloblast sending into the cord a fibre, *b*, which divides into ascending and descending limbs, *c*, *d*, and gives off collaterals, *e*, which embrace the cell *f* with their terminal filaments. This in turn sends off a nerve-process, *g*, which divides into ascending and descending limbs, *h*, *i*, provided with collaterals, *j*, *j*, that embrace with their filaments the motor cells *k*, *k*, from whose nerve-processes, *l*, *l*, the anterior roots are formed.

supposed to be connected either immediately with the posterior roots, or with Gerlach's plexus. (See Fig. 134, *K*.)

Cells with Short Nerve-processes (Golgi cells).—It was held by Golgi that these cells were confined to the posterior horn. This is found not to be the case. Still there is one locality in that horn, near Clarke's column, in which they are especially numerous. (Fig. 144, *g*.) They are also found near the anterior commissure, sending their processes across to the opposite side of the cord. (Fig. 144, *d*.)

Collaterals of the Columns.—We have hitherto considered only the collaterals given off by the ascending and descending limbs of the vertically-branching fibres of the posterior roots. These are by no means the only ones. A longitudinal section of the white columns in any portion of the cord shows that all the vertical fibres have the same disposition to give off to the gray substance collaterals that end by arborescent divisions. Kölliker could find no exception to this rule.

It is evident that these collaterals may arise from two sources: First, they may belong to column cells that have divided at higher or lower levels into their ascending and descending branches, and are sending back into the gray matter their terminals. These would produce what Kölliker has designated as the "indirect reflex path" by which the motor cells of different levels of the cord can be correlated in special groups (see Fig. 145); 2d, the collaterals may belong to nerve-processes of cells situated at levels entirely above the cord, in the cortex of the brain, in the cerebellum, or in the medulla oblongata. There seems to be some reason to think that this is the case. The so-called pyramidal tracts connect, as is well known, the motor area of the cerebral cortex with the cord. The result of degenerations shows that they are divided into two portions, the direct pyramidal tract, situated in the anterior columns, and the crossed pyramidal tract situated in the lateral column near the tip of the posterior horn. From each of these columnar areas collaterals pass in considerable numbers to ramify about the large cells of the anterior horn. It is interesting to note that, by the group of commissural cells situated on the medial side of the anterior horn, connection may be made with

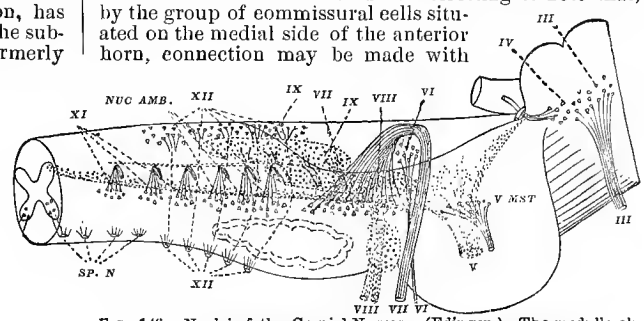

Fig. 146.—Nuclei of the Cranial Nerves. (Edinger.) The medulla oblongata and the pons are represented as if transparent.

the direct pyramidal tract of the opposite side, and that thus may be explained the fact, already demonstrated clinically, that lesions of this tract affect movements of the opposite side of the body.

Upon examining by the same method the nerves at a higher level than the spinal cord, we find that the same general structure is found. Some of the results obtained are most striking, and throw a flood of light on the general constitution of the nervous system.

The existing knowledge of the situation of the nuclei of origin of the cranial nerves is shown in the following diagram. (See Fig. 146.)

Olfactory Nerve.—In Fig. 147 there is diagrammatically shown an antero-posterior section of the olfactory bulb.

In the olfactory mucous membrane are found two kinds of cells, the epithelial, *ec*, and the nervous, *bc*, the latter being bipolar, presenting one process to the surface for the reception of impressions, while the other passes centrally and breaks up into the usual ramifications, forming the well-known glomeruli of the olfactory bulb, which have caused so much speculation. In these glomeruli they come in contact with the peripheral processes of another set of cells, called mitral cells from their shape, they having a large body and two processes given off nearly together. The peripheral process receives the stimulus from the olfactory glomeruli, and it is transmitted to the brain by the other process, which is directed horizontally. This shows in a striking manner that the hypothesis of Golgi, that the dendritic processes are for the purpose of absorbing nutriment, is incorrect. Each of the nervous elements or neurons is in fact independent, and each probably serves as a transmitter of stimuli.

Optic Nerve.—Here the sensory cells appear to be the large ganglion-cells of the retina. By their short processes they communicate with the special receptive elements, the rods and cones and the spongioblasts. Their long processes go to make up the principal mass of the optic nerve-fibres (see Fig. 148), and break up into the usual arborescent filaments that become associated with filaments of short-process cells situated within the central ganglia (corpus geniculatum, optic thalamus). The white radiations observed in the corpora geniculata are composed of such fibres. His has shown that in the embryonic retina there exist neuroblasts whose processes

grow centrally into the optic nerve. There are also in the optic nerve certain fibres that belong to cells situated in the corpora quadrigemina anteriora, and also probably some from cells in the occipital lobe of the cortex.

The question has been often discussed whether the fibres of this nerve between their real and apparent origin

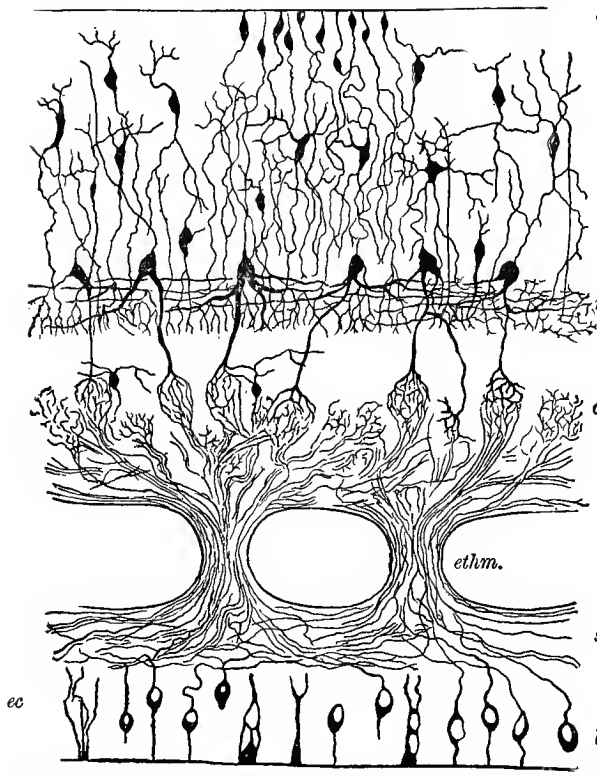

FIG. 147.—Structure of the Olfactory Filaments and Bulb. (Ramón y Cajal.) *bc*, Bipolar cells of the olfactory mucous membrane; *sm*, submucosa; *ethm*, cribriform plate of the ethmoid; *og*, olfactory glomeruli; *mc*, mitral cells; *ep*, epithelium of the olfactory ventricle; *ec*, epithelial cells of the olfactory membrane.

undergo a decussation either total or partial. Duval held that the fibres of the nerve proper do not decussate, but that there are mingled with them certain fibres from the posterior longitudinal bundle, probably derived from the nucleus of the abducens, that undergo decussation. This view was adopted and figured by Testut in his "Anatomie Humain," 1891.

Gudden showed, however that in the rabbit, and prob-

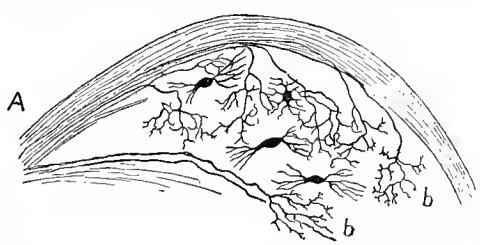

FIG. 148.—Connections of Fibres of the Optic Nerve. (Ramón y Cajal.) Section through the corpus geniculatum laterale of the cat. *A*, fibres of the optic nerve; *b*, *b*, their ultimate filaments eotwining with Golgi cells.

ably in man, the nucleus of the oculo-motor nerve is composed of two parts, one ventral, sending fibres to the nerve of the same side, one dorsal, sending fibres to the nerve of the opposite side.

Kölliker and van Gehuchten have recently studied the question anew, the former observer using the methods of Weigert and Pal, the latter that of Golgi. They find that in the duck, at least, there is a partial decussation of fibres derived from both the dorsal and ventral portions of the nuclei. The crossed fibres pass principally into the internal or median part of the peripheral nerve. The fibres of the posterior longitudinal bundle give off numerous collaterals that come in contact with the protoplasmic processes of the cells of the nuclei.

Starr divides the cells of the nucleus into groups which innervate special muscles, as follows:

Sphincter iridis.	Ciliary muscle.	Median Line.
Levator palpebræ.	Rectus internus.	
Rectus superior.	Rectus inferior.	
Obliquus inferior.		

Gaskell has put forward a theory that a ganglion formerly existed upon the third and fourth cranial nerves, and as evidence therefor shows a considerable mass of connective tissue, apparently the re-

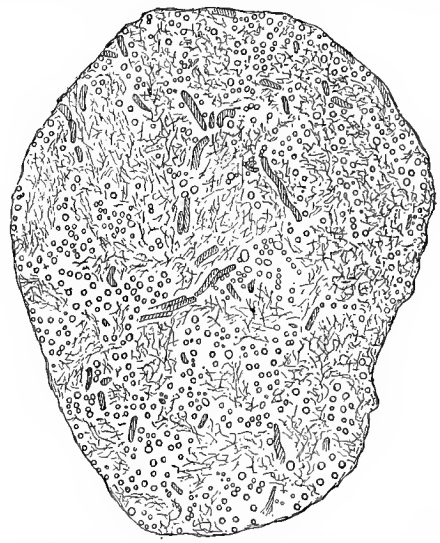

FIG. 149.—Transverse Section through a Rootlet of the Third Cranial Nerve of Man, to Show Degenerated Ganglion.

sult of degeneration, through which some of the rootlets of the nerve pass. He holds that the arrangement and appearance of these roots, as shown on section through this mass, is precisely that which would appear in a section through a ganglion. (See Fig. 149.)

He considers that this degenerated ganglion belonged to the sensory root of the nerve, and that this sensory root has disappeared because of the great changes that have taken place in the vertebrate head and brain. He also thinks that the substantia nigra of the crura cerebri is a degenerated nucleus from which arose certain lost fibres belonging to the third and fourth nerves.

He thinks the ciliary ganglion is a vagrant ganglion belonging to the small-fibred portions of the oculo-motor nerve.

Patheticus Nerve.—The evidence that the fibres of the fourth cranial nerve decussate completely has not in any way been shaken. Gaskell thinks that a small vagrant ganglion will be discovered in connection with it, as he believes it to belong to his efferent ganglionated splanchnic class.

Trigeminus Nerve.—Gaskell considers the motor-root of the trigeminus as a complete segmental nerve, that has its small-fibred ganglionated portion in the fibres that go to the spheno-palatine ganglion and whose sensory fibres have degenerated. The sensory root of the trigeminus he considers to belong to several of the segmental cranial nerves.

Abducens Nerve.—A novelty with reference to the origin of the sixth nerve is the discovery of a small and

easily overlooked bundle of fibres that turns toward the middle line ventrally from the nucleus and enters the abducens nerve of the opposite side. A connection has been described between the abducens nucleus and the superior olive. Edinger suggests that this connects the abducens with the auditory nerve and correlates the movement of the eyes with orientation in space. The connection of the fibres of the facial nerve with the nucleus of the sixth is definitely disproved by the researches of Gudden.

Facial Nerve.—Fibres from the facial nucleus are now known to decussate. The "superior facial nucleus" described by some authors as supplying fibres for the orbicularis oculi and frontalis muscles is now discredited. It is believed that these fibres, which do not degenerate in central disease of the facial nerve, are probably derived from the posterior longitudinal bundle.

Auditory Nerve.—A considerable addition has been made to our knowledge of the origin of the auditory nerve. It seems clear that we have here to deal with two nerves, one for the supply of the cochlea and one for the semicircular canals. Many physiologists hold that this latter nerve has nothing to do with hearing. The roots of these nerves lie on opposite sides of the restiform body and are therefore distinguished as lateral (superficial, inferior, posterior) and medial (deep, superior, anterior). The lateral is connected with the cochlear nerve, the medial with the vestibular.

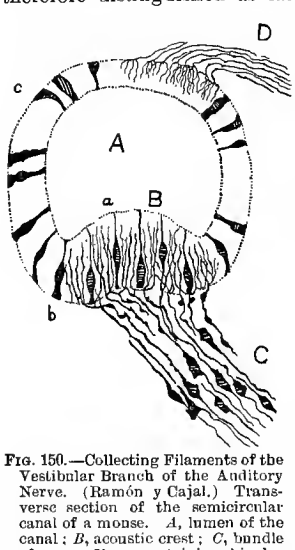

FIG. 150.—Collecting Filaments of the Vestibular Branch of the Auditory Nerve. (Ramón y Cajal.) Transverse section of the semicircular canal of a mouse. *A*, lumen of the canal; *B*, acoustic crest; *C*, bundle of nerve-fibres containing bipolar cells; *D*, a similar bundle supplying the top of the canal; *a*, *b*, and *c*, varieties of bipolar epithelial cells.

The lateral root springs from a collection of cells lying partly outside the brain substance, like a ganglion on a nerve-trunk. In some vertebrates and in the embryo it is wholly detached. It is sometimes termed therefore the auditory ganglion. It produces the eminence in the medulla oblongata known as the acoustic tubercle.

The medial root arises chiefly from a large nucleus lying near the median line known as the chief auditory nucleus, also from a collection of large cells lying more externally, termed Deiters's nucleus.

By the method of Golgi, Retzius has shown that the endings of the auditory nerve are essentially the same as those described for other sensory nerves. Both in the organ of Corti and in the acoustic crest of the semicircular canals exist the terminals of bipolar cells situated in the ganglion spirale (cochlear nerve) and ganglion of Scarpa (vestibular nerve), which terminals break up into numerous branches situated between the epithelial cells. The epithelial hair-cells represent, then, the same elements as the rods and cones of the retina, and are agents for carrying to the nerve-cells the sonorous vibrations. This arrangement will be seen in Fig. 150. The epithelial expansion of this bipolar cell corresponds apparently to a dendritic process, while the central communication is an axis cylinder. *Frank Baker.*

CREASOTE. Discovered in 1830 by Reichenbach it early acquired a reputation for being of service in pulmonary troubles, and has always been used to a greater or less extent in such diseases. Its recent revival, however, dates from the communications of Professor Julius Sommerbrodt, of Breslau, Fraentzel, Guttman, and others in 1887 and 1888. Ten years previously Drs. Bouchard and Gimbert had given the results of their experience with the drug, and had recommended that it should be more extensively used in pulmonary phthisis, as it had proved of decided valne in their hands. During the intervening years many physicians tried the remedy, but it was not until Professor Sommerbrodt corroborated the statements of Bouchard and Gimbert, and claimed for it even greater curative properties, that it received the attention which it appeared to deserve. Sommerbrodt's experience appears to have embraced many thousand cases and to have extended over a number of years ; as a result he is very decided in his views, and claims that it is not only a very useful drug for the relief of the numerous troublesome symptoms, but that, by its power of checking the progress of the disease, it appears to possess almost specific properties. In a later paper, in reviewing some five thousand cases of tubercular disease, he states that definite recovery has been attained in a much greater proportion than by any other method of treatment, and in the great majority of cases decided benefit could be traced to its use. The fever, night-sweats, cough, and expectoration were lessened, the general health of the patient improved, and in the cases where no curative effect followed or was to be expected, the lives of the patients were prolonged and rendered more comfortable. He dwells particularly upon the importance of an early diagnosis where curative results are to be expected, and insists upon the drug being administered in full doses and for a prolonged period. In his early cases he considered five to eight minims a day to be sufficient, but he now advises that as much should be given as the patient can bear, his rule being that the more creasote can be introduced into the system the greater will be its beneficial action. He now advises that twenty to twenty-five or thirty minims a day should be given, and this dose continued for many months or even years. His mode of administering it is to commence with one minim three times a day and increase the dose by one minim each day for eighteen days, until such an amount is reached as the patient can bear, and then continue that quantity for an indefinite period. He gives the drug with a few drops of cod-liver oil or oil of sweet almonds in capsules,—never on an empty stomach, but after the three principal meals. The purity of the drug he considers of the greatest importance, and advises that only the best beech-tar creasote be used. If these points are observed no difficulty should be experienced by the patient, as any ill effects—such as eructations and belching of wind—never continue for any length of time. The antiseptic action improves the condition of the digestive tract and a decided improvement soon follows its use, not only relieving the digestive disturbances but increasing the appetite and promoting assimilation and the general well-being of the system. Another advantage that he claims for this treatment is, that it is simple and devoid of danger and does not prevent the adoption of further methods of combating the disease.

Sommerbrodt's purpose in administering the drug so freely is based upon the researches of Guttman, who found that the bacillus of tuberculosis would not live in a solution of greater strength than one part in four thousand. He points out that if about twenty grains could be introduced into the blood of an ordinary man it would represent a solution of such a strength. He considers it possible to produce such a condition by giving it in large quantities, as it is not likely to be changed or excreted as rapidly as it is introduced. He has given as much as sixty minims a day, and Freudenthal has pushed it to one hundred and fifty minims in the twenty-four hours.

How creasote acts or in what way it produces its beneficial action has not been determined. It is admitted that the improvement in digestion and nutrition that follows its use places the system in a better state to resist the disease, but beyond this nothing is known. Creasote does not exist in the blood in a free state, and this would seem a serious objection to Sommerbrodt's theory, but it is supposed to enter into combination with certain albuminoids in the blood, and this combination he considers still possesses the properties of the crude drug. Very recently Seifert and Hoelscher have formulated a theory which favors this view : they conclude that the products of creasote circulating in the blood render innocuous the ptomaïnes which have been formed by the bacilli and afterward absorbed. In this way it eliminates from the system these toxic compounds before they produce any of their deleterious effects.

Such experiments as have been made on animals to test the efficacy of creasote upon tuberculosis have not supported the views of those who consider it of so much value. The disease always progressed steadily, and no effect was apparently produced by the drug. Sommerbrodt, however, points out that artificial tuberculosis in animals is very different from the disease in man, and that many animals are particularly susceptible to the influence of the poison.

In using creasote much difficulty has been found in administering the large doses that are advised without producing gastric disturbance and causing the patient to rebel. How far this may be due to the quality of the drug is hard to estimate, but it may also be, to a certain extent, due to the preparation or the manner in which it is given. Mixed with the oil and enclosed in capsules is probably one of the simplest, as well as easiest ways of taking the drug. When the cod-liver oil is not well borne, the more bland oil of sweet almonds or olive-oil may be employed. In addition to the nutritive properties of the oil, it is supposed, to a certain extent, to convey the drug into the intestines before being acted upon. Freshly prepared capsules are always to be preferred, as it has been found that a chemical reaction occurs when the oil and creasote remain in contact for any length of time. Dissolved in spirits is a common way of prescribing the drug, and tincture of gentian has been favored as a means of disguising the taste. A combination of Bouchard, which has given rise to many modifications, was as follows : Creasote, 15 minims ; tincture of gentian, 40 minims ; rectified spirits, 6 drachms ; white wine, to make 3 ounces. Milk is recommended as a good vehicle for the drug, either in its purity or when in solution. Malt extract, or malt extract and emulsion of cod-liver oil, are very highly praised as a means by which it may be administered. The following emulsion is said to disguise the taste and supply the beneficial properties of the constituents : Malt extract and emulsion of cod-liver oil, 8 ounces ; creasote, 80 minims ; oil of bitter almonds, 4 minims ; oil of lemon, 6 minims.

Many pills containing creasote are prepared and form a convenient vehicle, but the insolubility of many of these pills must not be forgotten. A coating of keratin, resin, salol, collodion, and substances not acted on in the stomach, is now prepared, and the creasote is only liberated when the pill reaches the alkaline fluids of the intestine.

The hypodermic injection of creasote has been advocated as an excellent means of introducing it into the circulation, the great advantage being that it does not cause any derangement of the digestive organs. A ten per cent. solution in oil of sweet almonds is used, and the treatment begun by injecting small amounts, which are gradually increased. Local irritation, however, has frequently followed, and the internal administration is generally preferred when possible. Deep pulmonary injections have been used. Specially prepared long needles are employed, and the creasote carried through the chest-wall directly to the diseased tissue. Eight minims of a

three per cent. solution in oil is the quantity used. A modification of this is the intra-tracheal injection of the drug. A five per cent. solution in oil of almonds is used, and thirty-one minims (two grammes) injected into the trachea twice a day. The oil descends into the lungs and gradually enters the alveoli. It is said that no bad effects follow this use of the drug, and on the affected part a beneficial local action is exerted.

Inhalation is, of course, a valuable way of acting directly on the diseased organ, and forms an important adjunct to the internal use. The following combination is most efficient: Creasote, eucalyptus, and turpentine, each 5 drachms; iodoform, 7½ grains; dissolved in sulphuric ether, 1¼ drachm.

In a paper published by Professor Sommerbrodt within the past year the application of creasote is specially advocated in the glandular enlargement and other diseases arising from a tuberculous condition in children. With him the results of such treatment have been most favorable, and he urges others to adopt it in their practice. The dose for children above six years of age is from 7 to 12 minims per day, beginning with one minim and increasing it daily, as in his former directions for pulmonary disease. He also takes advantage of the occasion to insist upon the importance of a full dosage, and reiterates his faith in its value.

In this paper he records the first instance of profound intoxication by the drug that has been brought to his notice. A patient of Dr. Freudenthal, of New York, who was taking, with benefit, from 30 to 45 grains a day, took about 150 grains (9 or 10 grammes) within two hours. She became unconscious, and gave the impression of one narcotized; pulse, 128; respiration, 30; intense trismus, lips cyanotic, pupils contracted, sensory and reflex action annulled. After nine hours the patient recovered without any ill effects following, and continued the regular use of the drug.

Although it is now very evident that no toxic effects are to be dreaded during proper medication, there are some symptoms that must not be disregarded. The discoloration of the urine, when it occurs during large doses, calls for a diminution of the quantity, or its stoppage for a short period; but if it follows small doses, or occurs frequently, the drug must be given very cautiously. Vertigo, intoxication, and signs of stupor must not be disregarded, and malaise, prostration, sweating, cephalalgia are also signs of intolerance of the drug.

Beaumont Small.

CREOLIN is a proprietary article, the name being registered by the manufacturers in Hamburg. Commercial creolin, however, varies much in appearance and properties, and many preparations are sold under that title. It is obtained from the product that remains after carbolic acid has been removed during the fractional distillation of coal-tar. The cresols form the active ingredients. The following analysis of the German compound is furnished by Dr. Bernard Fischer: Cresols, 20 parts; naphthalene, 18 parts; other hydrocarbons. 20 parts; and non-volatile matter, 42 parts. It is quite free from carbolic acid and other poisonous ingredients, and should not possess any toxic properties. Creolin is prepared by treating these insoluble hydrocarbons with resin and caustic potash, which form a resinous, soapy emulsion. When added to water and agitated the ingredients remain suspended as an emulsion. In appearance it is a dark, resinous liquid, neutral to test-paper, not caustic. Its odor resembles creasote. It mixes with oils.

It possesses powerful antiseptic and disinfectant properties, and is recommended as a substitute for carbolic acid, to which it is said to be superior, as it does not contain any poisonous ingredients. It is very extensively employed, and numerous reports speak in its favor in all conditions where carbolic acid is indicated.

For surgical purposes two solutions are employed, one containing two per cent. of the drug, the other one-half per cent. The stronger is used for disinfecting the hands, the instruments, and surfaces of the body; the weaker solution is used for irrigation, moistening dressings, saturating tampons, etc.

For suppurating and sloughing wounds, and where discharges are offensive the parts may be cleansed and disinfected by the pure drug, and the effect maintained by a weaker solution. To irrigate the bladder, urethra, nose, pharynx, and other mucous surfaces, a solution of one part in a thousand is sufficiently strong.

The objections to its use are, the uncertainty of its action on account of the numerous preparations, and being unctuous it renders the hands and instruments slippery and difficult to handle. *Beaumont Small.*

CRESALOL. This is the cresylic ether of salicylic acid, and bears the same relation to cresylic acid that salol does to carbolic acid. It is analogous to betol and salol, and has been introduced by Nencki, the originator of the other two compounds. It is prepared by treating cresylate of sodium and salicylate of sodium with perchloride of phosphorus. Three salts are formed, according as the ortho-, meta-, or para-cresylic acid is used. All three possess the same properties, but the para-cresalol is the one usually prepared. The chemical formula is $C_6H_4OHCOC_6H_4CH_3$.

Cresalol is a white, crystalline powder, without taste; odor somewhat resembles salol. It is insoluble in water, slightly soluble in alcohol. The dose is given as from three to thirty grains daily. It possesses antiseptic properties similar to salol, and, like that salt, is not acted upon by the secretions of the stomach. It is used for intestinal antisepsis, and is said to be more efficient than its analogues. In the system it is decomposed into cresol or cresylic acid and salicylic acid, and its advantage is the freedom of these acids from any toxic properties.

Beaumont Small.

CRESOL, CRESYOL, CRESYLIC ACID. This consists of ortho-, meta-, and para-cresylic acid in variable proportions, having a general formula of C_6H_4, CH_3, OH. It is a higher homologue of carbolic acid or phenol, and differs from it by the replacing of one atom of hydrogen by the methyl group CH_3. It is present in coal-tar, with carbolic acid, and is obtained during the process of fractional distillation. The fractional distillation of coal-tar consists in the separation of groups of products according to their volatile properties. Up to 80° C. about four per cent. is separated, consisting of carbon bisulphide, ammonia, amylene, benzene, and other very volatile compounds. From 80° to 210° C. what is termed the light oil is removed; this is made up of benzene and its homologues. Between 210° and 400° C. the heavy oil is formed, consisting of phenol, naphthalene, cresols, and other hydrocarbons. The residue is pitch, about fifty per cent. The phenol, cresol, and naphthalene, and other constituents of the heavy oil, are separated by further distillation. It forms the greater part of the crude carbolic acids of commerce, which might more properly be called crude cresols.

It is a colorless, strongly refractive liquid, boils at 397° F., is strongly caustic; its odor resembles creasote. It is insoluble in water, soluble in alcohol, glycerine, and ether. The cresols are powerful antiseptics and produce some of the most active preparations of the aromatic series. According to the investigations of Jaeger and Ohlmüller, of the Board of Health, and Fraenkel, of the Berlin Hygienic Institute, it has been shown that when dissolved in sulphuric acid the most active of such antiseptics is formed. Being insoluble in water it is difficult to obtain a solution that is stable and applicable to surgical purposes.

Many methods have been devised and numerous preparations have been introduced into commerce under a variety of names: creolin, lysol, solveol, solutol, and others, are all preparations of this kind. Some contain other hydrocarbons in addition to the cresols. Resin and alkali soaps form a favorite means of retaining the active ingredients in solution, but when added to water they produce milky and greasy fluids, very objectionable for surgical uses; the antiseptic properties are, however,

effective as deodorizers and disinfectants. Cresotate of soda has been found to retain cresol in solution. For therapeutic purposes a one and one-half per cent. solution is sufficiently strong, free from irritant or caustic properties, and equal to a five per cent. solution of carbolic acid. Cresol is also dissolved in a concentrated solution of salicylate of sodium, which allows of free dilution; no decomposition occurs, a neutral solution of cresol being formed. Lime is recommended as a means of rendering a solution which forms a cheap and active disinfectant; one part of lime is treated with four parts of water, and five parts of cresol are added; the resulting liquid contains fifty per cent. of cresol and is miscible in water in all proportions.

For internal administration the preparation cresalol has been introduced and is highly recommended.

Beaumont Small.

CRESOTIC ACID (*Cresotinic Acid, Homosalicylic Acid*). This is a higher homologue of salicylic acid, to which it is allied both in chemical and in physiological properties. Its formula is $C_6H_3OHCH_3COOH$, which is that of salicylic acid, $C_6H_4OHCOOH$, with one atom of H replaced by the methyl group CH_3. It is obtained by the action of carbon dioxide on sodium and cresol; the product, when treated with hydrochloric acid, yields a solution of cresotic acid, from which it is separated by evaporation. It crystallizes in long, white, prismatic needles, which dissolve with difficulty in cold water, more readily in hot water, and are very soluble in alcohol, ether, and chloroform. Three isomeric acids are formed—the ortho-, meta-, and para-cresotic acids,—corresponding to the ortho-, meta-, and para-cresols. They differ in their melting-points, by which they may be distinguished, that of the ortho being 160° C.; the meta, 177° C.; and the para, 151° C. Their aqueous solutions are colored violet by ferric chloride, and in many other reactions they correspond to salicylic acid. They are now most readily separated from this acid by the fractional crystallization of their lead salts from alcoholic solutions. The three acids are generally present in the salicylic acid of commerce, which is prepared artificially, as much as 8.10 per cent. of the para-cresotic acid having been detected in some specimens. They are never present in the natural acid prepared from the oil of wintergreen.

These acids were brought to the notice of the profession in 1890, as dangerous ingredients of the salicylic acid of commerce, by the researches of Professors Charteris and Dunstan, of Glasgow, which were published in the *Pharmaceutical Journal and Transactions* of November 22d. It had long been known that very alarming symptoms often followed the use of the artificial salicylic acid, and in 1878 two bodies had been separated which had been shown to account for the toxic symptoms, but which at the time were not identified. These were now demonstrated to be ortho- and meta-cresotic acids, and the third acid was also found to be present in large quantities. The meta-cresotic acid was known to be inert, but it was now claimed that both of the other two possessed a powerful depressant action on the heart, and in comparatively small doses would produce fatal effects when given to animals. These statements, particularly in regard to para-cresotic acid, were important, as this acid was supposed to be less toxic than salicylic acid, and had been recommended to be used in medicine as a substitute. To verify those statements further experiments were made by Professor Charteris, and the results were published in the *British Medical Journal* for March 28, 1891.

His experiments proved that both acids were active poisons, and rapidly caused death when administered to animals by means of an hypodermic injection. His conclusions are that the lethal dose of the para-cresotic acid is about three grains per pound-weight of the animal, and that one grain of the ortho-cresotic acid would have the same effect. These doses were fatal within three hours, the toxic symptoms following immediately upon the use of the drug, and he considers that much smaller doses would also prove fatal, but after a more prolonged interval. Further experiments were made by combining the two acids, and it was found that the fatal quantity was less than when they were administered separately. The acids were also used when added to pure salicylic acid, and this combination added to the toxic power of the cresotic acids. One grain of para-cresotic acid and one grain of the ortho-cresotic acid were dissolved with twenty grains of salicylic acid, and experiments showed that one-quarter of a grain of each cresotic acid, with four and one-half grains of salicylic acid, proved fatal to an animal weighing two pounds.

Chemical experiments were also made which led to important results, and proved how essential the degree of crystallization and the melting-point are as means of indicating the purity of salicylic acid. He found that when either of the cresotic acids was added to pure salicylic acid, dissolved and recrystallized, the departure from the large and beautiful crystals of the latter was in direct ratio to the degree of contamination, and when the amount of impurity was great, an amorphous powder was the result, and the acids had to be redissolved several times before crystals could be obtained.

The practical conclusion to be drawn from this is, that the difference in degree of crystallization allowed by the Pharmacopœia between the natural and artificial salicylic acid allows a certain percentage of the cresotic acid to be present. With regard to the melting-point, it was also shown that 156.8° C., allowed by the British Pharmacopœia, was too low, and permitted the same impurities to be retained. The experiment showed that an artificial acid could be prepared as pure as that obtained from the natural sources, and it was urged that in the revised Pharmacopœia these tests should be insisted upon and the standard of purity raised. The following is a tabular statement of the results of experiments made to determine the melting-point of the various mixtures:

Natural salicylic acid of commerce	157.0° C.
Artificial salicylic acid of commerce	156.0° C.
Equal parts of salicylic acid and other cresotic acid, dissolved and crystallized	136.0° C.
Equal parts of salicylic acid and para-cresotic acid, dissolved and crystallized	128.5° C.
Twenty grains salicylic acid and one grain ortho-cresotic acid, dissolved and crystallized	152.5° C.
Twenty grains salicylic acid and one grain para-cresotic acid, dissolved and crystallized	152.0° C.
Sixty grains salicylic acid and one grain ortho-cresotic acid, dissolved and crystallized five times	156.0° C.
Sixty grains salicylic acid and one grain para-cresotic acid, dissolved and crystallized six times	154.5° C.
Ninety-seven grains salicylic acid, two grains para-, and one grain ortho-cresotic acid, dissolved and crystallized	155.0° C.

The only preparation of these acids that has been prepared for therapeutic purposes is the para-cresotate of sodium. It is a white, fine, crystalline powder, with a slightly bitter taste, soluble in twenty-four parts of warm water. It is said to possess antipyretic and antirheumatic properties similar to those of salicylate of soda, but in a lesser degree. It, however, has the advantage of not disturbing the digestive organs. Although it has been shown that the acid base has such decided toxic properties, this salt is said to be quite harmless, and may be given in doses of forty-five grains a day, for several days in succession, without any ill effects. The dose recommended is, according to the patient's age, from one and one-half grain to twenty-three grains, repeated three or four times a day. It is also reported to be of use as an antipyretic in pneumonia and typhus fever. In children it has been used in gastro-intestinal catarrh as an intestinal antiseptic.

Beaumont Small.

DAWLISH. A popular and pleasant seaside resort in Devonshire, England. It is about equidistant from Exmouth and Teignmouth. The English patronize the place at all seasons, but its chief attraction is a fine beach which is used in summer. The climate is not as equable and mild as that of Torquay, nor is the place as fashionable and expensive. Dawlish rests on gravelly soil, which, in view of the large amount of rainfall, is obviously a great advantage. It is cooler in summer than the resorts nearer London. The climate is humid, and,

while sedative, is rather relaxing. The indications are the usual ones for healthy seaside resorts; and the place is especially to be recommended for those conditions which a too bracing climate might injuriously affect. It is not an international resort, being visited by the British only. *Edmund C. Wendt.*

DEATH, ORIGIN OF. PHYSIOLOGICAL THEORIES.—Living things, in the forms most familiar to us, at least, all grow old and die. We infer that this fate is universal with something of the same certainty with which we prophesy that a stone thrown into the air at any spot whatsoever will fall back again to the earth's surface. On the other hand, it is equally a commonplace of observation that the death of the individual does not mean the death of the race, and, inasmuch as every living thing is directly sprung from a preceding form,—*omne vivum e vivo*,—we may assume that the continuity of life has never been interrupted, and never will be. If the environment remains as favorable in the future as it has been in the past, living things will continue in unbroken succession for all time. From this stand-point we may speak justly of living matter as possessing immortality, or, at least, potential immortality, since it has unlimited powers of propagation. It is one of the final aims of biological speculation to reconcile these two apparently paradoxical properties of living matter; to furnish a satisfactory hypothesis which shall explain the occurrence of old age and death in the individual, and at the same time account for the possibility of unending existence for the race, which is implied in the fact of reproduction.

In speculations of this character we must, moreover, keep clearly in mind that forms of living matter are not stable, in the same sense that forms of dead matter are. A given animal exists for a period of five years; but we are all perfectly well aware that no portion of the living substance of this animal has remained actually the same throughout this time; *i.e.*, the atoms of C, H, O, N, S, P, which constituted the living matter in the beginning, were replaced very early by others brought in with the food. What has remained unchanged through the individual's life has been, on the physiological side, a form of activity, and, on the morphological and chemical side, a material substratum of a practically definite composition. However familiar this fact may be, it is, after all, the great distinctive feature of life—or rather, of living matter. We express in the single word assimilation, or nutrition, that property which separates living matter from dead. As long as any particle of matter is in the living form, just so long has it the creative power of converting dead food into living substance like itself. Throughout its period of existence there is a steady stream of dead matter coming to it to be rearranged into the living form, and an equally continuous outflow of dead material from it which had once been in the living form. Nothing can make this conception clearer than Huxley's simile of the whirlpool at Niagara,—which fits so well as an illustration of the ever-changing particles which make up the unchanging form of life. From this point of view we may say that living matter is never actually the same, yet it must be evident that, in respect of any given mass of that body which we call protoplasm, it can only reproduce itself in its offspring by transmitting a portion of its actual substance. The formation of a new organism from this transmitted germ is therefore, from a chemical stand-point, no more a creation of a new being or of new living material, than is the continued existence of the parent form throughout its period of natural life.

As far as the mere external phenomena of senility are concerned they may be observed and recorded. In the human being this has been done with more or less care. The coming on of the signs of old age in the different tissues, the rate of its normal development, and the conditions which hasten or retard its development, are known to a certain extent, though they have not been investigated with the carefulness of detail which scientific exactness requires. We cannot expect any solid advance in our knowledge of the development of old age until the statistics, which may be determined by experiment and observation, have been recorded. The superficial signs of old age are spoken of usually in the text-books of physiology. In the old, the bones become more brittle because of a continually increasing excess of deposits of inorganic salts; the cartilages become more rigid and calcareous for the same reason; the elasticity of the lens of the eye decreases, bringing on imperfect accommodation; the muscles atrophy and lose their physiological mobility, as shown by the lessened vigor of their contractions and their diminished elasticity; the hairs lose their pigment, etc. It is important to notice that these signs of deterioration in the machinery of life do not make their appearance first during or after the period of maturity, but begin to develop from the time of birth, or possibly before. At ten years of age the near point of distinct vision is 7 ctm. from the eye, at twenty it has lengthened to 10 ctm., at forty years of age it is 22 ctm., at sixty years it is 100 ctm., and so on. The long-sightedness of old age begins to develop in early childhood, and results physiologically from a continual diminution in the elasticity of the lens. We obtain similar facts if we measure the rate of growth of the body throughout life. According to the somewhat unreliable statistics of Quetelet, the average male child weighs at birth 6½ pounds. At the end of the first year it will weigh 18½ pounds, a gain of 12 pounds. At the end of the second year it will weigh 23 pounds, a gain of only 4½ pounds. And so on to full maturity the rate of increase each year falls rapidly. If we measure the rate of growth by the increase in height instead of by the increase in weight, we find that in the first year the gain is 148 mm., in the second year it has fallen to 93 mm., in the third to 72 mm., from the twentieth to the twenty-fifth year it averages 12 mm., and from the twenty-fifth to the thirtieth year only 0.8 mm., while in extreme old age it becomes a negative quantity. In a recent paper Minot has given the results of a laborious research upon the growth of guinea-pigs, which show much more clearly and accurately the same general fact of a decrease in the rate of growth beginning shortly after birth. Minot bases his figures upon observations taken daily. He defines the term "rate of growth" with an exactness not hitherto employed, in that he calls attention to the fact that usually, in considering the rate of increase, the actual increment at different periods is given instead of the proportionate increment. In other words, if an animal in successive periods gains in absolute quantities only the same amount in weight or height, its rate of growth is in reality decreasing, since proportionately to the weight of the whole animal the increase has been less and less. Making use of his short periods of twenty-four hours, and expressing the rate of growth as the fraction of weight added during that period, he finds that, after the animal recovers from a short postnatal retardation of growth, the rate of growth diminishes during life, at first rapidly, and afterward more slowly. It follows from these facts, that what we may call the creative power of growth, or better, the creative power of assimilation, which measures the capacity of living matter to form matter like itself, decreases steadily from birth. Like a stone projected upward, the initial velocity begins to fall from the outstart. As the height to which the stone travels may be taken as a measure of the force with which it was thrown, so the length of life in any individual may be taken as a measure of the power or capacity of assimilation with which the germ of that individual started its career. When the power of assimilation is insufficient to replace the wastes of nutrition then death for that tissue is at hand. Whatever may be the internal causes which lead to this diminution, and thus serve to bring on old age, we are safe in saying that they begin to make themselves felt in the very first years of postnatal life. The curve of vitality—to use a much-abused but convenient word—does not rise from birth, reach its maximum in the vigor of maturity, and fall in old age, but begins to fall steadily, though not uniformly, from the beginning of life.

To mankind as individual organisms old age and death are inevitable, but it is interesting to inquire what may

be considered as the longest possible life under the most favorable conditions this world is likely to afford. We can answer this only by searching the records. If we put aside the oldest accounts on the ground of uncertainty as to the unit of time, and make our estimates on the basis of comparatively modern statistics, we may put the maximum age as lying somewhere between one hundred and twenty and one hundred and eighty years. Perhaps the most celebrated case of longevity is that of Thomas Parr, an account of whose life, together with the results of a post-mortem examination made by Harvey, may be found in the third volume of the "Philosophical Transactions," p. 886. The account relates "that he was a poor countryman of Shropshire, whence he was brought up by the Right Honorable Thomas, Earl of Arundel and Surrey, and that he died after he had outlived nine princes, in the tenth year of the tenth of them, at the age of one hundred and fifty-two years and nine months." Other interesting extracts from the letter of Harvey are as follows: "The cartilages of the sternum were not more bony than the others, but flexile and soft." "The cause of his death was imputed chiefly to the change of food and air; forasmuch as coming out of a clear, thin, and free air, he came into the thick air of London, and after a constant, plain, and homely country diet, he was taken into a splendid family where he fed high and drunk plentifully of the best wines." "He was able, even to the hundred and thirtieth year of his age, to do any husbandman's work, even threshing of corn." It is also stated that he married a widow when one hundred and twenty years of age, and from her own statement had frequent sexual intercourse with her. In an essay by Pflüger on macrobiotics, he refers to other recorded cases of unusual longevity. H. Jenkins, a native of Yorkshire, died, in 1670, at the age of one hundred and sixty-nine. It is related that on one occasion, when brought before a justice to testify with reference to an event which had occurred one hundred and forty years before, he appeared accompanied by his two sons, aged one hundred and two and one hundred years, respectively. A more remarkable case still is that of Kentigern, or Saint Mungo, founder of the Cathedral of Glasgow, who reached an age of one hundred and eighty-five, if we may trust the accounts of his life on record. Among the exceptional cases recorded some are stated to have been unusually temperate in their habits of life, while others paid no regard to such precautions. In this last category Pflüger mentions one Brawn, who reached an age of one hundred and twenty, although his tombstone records the fact that he was a confirmed drunkard. Outside of such evidence as this, it is evident that exceptional longevity cannot be referred solely to careful observance of hygienic conditions. We must explain it, in general terms, as due to an unusual power of assimilation in the living substance composing the tissues, and that this tendency to long life is inherited may be accepted as demonstrated by the statistics of life insurance. At the present day we have numerous cases of persons passing the hundred-year mark by a few years, so that this age cannot be regarded as very unusual.

However, leaving aside the reproductive cells, death sooner or later comes to the rest of the cells of the body, no matter how favorable the environments of life may be. It is not altogether hopeless to inquire into the causes which bring this about, though naturally any such investigation is largely made up of speculation of a very general character. We may define death as a cessation of life. In order, therefore, to arrive at even a general conception of its cause one must first define as clearly as possible what is meant by life. Spencer's definition is perhaps the one most familiar to educated persons. According to him life is the continual adjustment of internal to external relations. When properly analyzed the definition includes a great deal, and it is difficult to criticise it justly. But the physiologist will certainly object to it, because it attempts to present, in the most general terms, only the *ensemble* of properties manifested by living matter without pretending to trace these properties in any causative way to the physical substance which manifests them. It is as though one defined light by enumerating its chemical and physiological effects instead of referring it to vibrations of the ether. For the physiologist an adequate definition of life must be one which connects its phenomena with the chemical structure of living matter. As the chemist may deduce the chief properties of a salt from a knowledge of the structure of its molecule, so the physiologist believes that a scientific explanation of life—that is, of the phenomena of assimilation and reproduction—can only be obtained by discovering the essential chemical structure of the living molecule. To this end all biological work tends. The adjustment of internal to external relations, and the interaction of the different organs which brings about this adjustment, should be deducible from the chemical structure of living matter in somewhat the same way that the adjustments or reactions of benzine to different external conditions may be foretold from a knowledge of its molecular structure. That this kind of explanation of life is not inconceivably remote is demonstrated by the fact that several chemical theories have been seriously proposed and applied in some detail. Pflüger, for example, suggests that the essential difference between dead and living albumin lies in the grouping of the nitrogen in the molecule. In dead albumin it may exist in the form of an ammonia compound, while in albumin which is living it occurs in part, at least, in the cyanogen grouping. As something approaching scientific evidence for this view he asserts that the oxidation products of dead albuminous bodies—that is, as far as the nitrogen is concerned—are always ammonia compounds, amines, or amido-acids, while the end products of the oxidations of living substances may be classed among the cyanogen bodies. Moreover, the cyanogen compounds are characterized by their instability, and this is likewise one of the most prominent phenomena exhibited by living substances; it is doubtless the chemical cause of what is known as the irritability of living things. Cyanogen compounds also exhibit, in a striking way, a tendency to polymerize, and Pflüger suggests that this property of polymerization may be the essence of what we speak of in general as assimilation or nutrition, by which the living molecule takes into itself the molecule of dead albumin. Indeed, says Pflüger, we may may look upon the molecule of cyanic acid as showing properties intermediate between those of living and dead matter, as a half-living substance. In a similar way Loew and Bokorney attempt to explain the peculiar properties of living matter on the supposition that its molecule contains an aldehyde group. They find that living protoplasm, in certain plant-cells at least, has the property of reducing silver nitrate from alkaline solutions, while dead proteid has no such action. They infer that this reducing power is caused by the presence of an aldehyde group, and they give a scheme showing that formic aldehyde, by union with ammonia, may produce aspartic aldehyde, and this, by condensation and reduction, with the addition of S, will give, or might give, a compound of the molecular formula of proteid, which as long as it retained the aldehyde grouping would be living proteid, and would form the basis of living protoplasm. Latham attempts to combine the theories of Loew and Pflüger by supposing that living proteid is composed of a chain of cyan alcohols, united to a benzine nucleus, thus explaining the irritability or instability of living proteid, as well as its reducing action. However inadequate and premature such hypotheses may seem at present, they at least serve to demonstrate the fact that the physiologists and chemists are looking forward to a definition of life based upon a knowledge of the chemical structure of the substance through which it is made manifest.

Proceeding from his conception of what constitutes life, Spencer defines natural death as a want of correspondence between the internal and external relations. Perfect correspondence would mean eternal existence.

If the organism could adapt itself to every change in its environment, old age and death would be impossible. It is difficult to understand the full significance of Spencer's language. Taken literally it seems to assert noth-

ing more than that death is a cessation of life. It adds nothing at all to our knowledge of the causes leading to this cessation, nor does it indicate any fruitful line of investigation. If, however, Spencer means that the fatal want of correspondence may come from without; that is, from changes in environment to which no adequate adaptation can be made by the organism, and in many passages this seems to be implied, then his view is opposed to that accepted by most physiologists. They, the physiologists, believe in general that although the environment were perfect and unchangeable, yet by virtue of inherent changes in the organism itself the assimilative powers would inevitably grow weaker and finally cease with death. In want of a more exact knowledge of the structure of the living molecule and the changes in structure which come on in old age, the physiologist expresses his ideas of the general nature of these changes by similes and metaphors more or less apt. We may compare the living organism to a clock, the mainspring of which is so constructed that in consequence of slowly developing molecular changes it suffers a gradual loss of elasticity. In such a mechanism there will come a time when "winding the clock up" will no longer make it run, since energy can no longer be stored in the spring. We may imagine this loss of elasticity to develop gradually, giving stages that may be roughly compared to the periods of life. To carry out the simile, it is the food we eat and the oxygen we breathe which take the place of the winding force. In consequence of a slowly developing molecular change in the organism, this energy is less efficiently utilized as the individual grows older. The clock runs more feebly and needs relatively more frequent winding, until at last the elasticity is gone, the power of assimilation is insufficient, and we have what we call natural death. In complex organisms like ourselves this failure of assimilation may come first to some one organ, such as the heart or the nervous system, and through its collapse the organism as a whole ceases to exist. In the nature of the case natural death cannot come to every organ of the body at the same time, so that the death of a portion, perhaps from the stand-point of weight, the larger portion of the body, must always be accidental, as, for example, from a shutting off of the blood-supply due to natural death of the heart. But this consideration does not affect the general conception of the liability of all the organs to a similar fate. Rightly or wrongly, it is, or has been, a well-nigh universal belief that every organism and every bit of living matter in an organism has only a limited duration of life, no matter how favorable the external conditions may be.

In striking opposition to this view, Weissmann, in a recent series of essays upon the duration of life, has attempted to demonstrate the essential immortality of living matter, or, in other words, to show that death is not an inherent necessity of life, but an acquisition or adaptation on the part of living things. These essays have aroused a wide-spread interest and discussion among biologists, and are probably the most important speculations of recent times upon the origin and meaning of death. Weissmann carries the problem back to the lowest forms of life, the unicellular organisms or protozoa. Whatever in this regard is true of them must be looked upon as being or as having been true for living things in general, since modern biological doctrines trace the evolution of life from these forms, and modern morphology has demonstrated that all complex forms of life are in fact mere colonies or collections of unicellular organisms. If we study one of the protozoa, the amœba for instance, which has always been taken as the archetype of life, we find that it is a complete cell; that it feeds, and assimilates, and excretes; that it increases in size, and finally reprodnces by simple fission, forming two new individuals, or daughter-cells. In this last process we have the disappearance of one old individual and the formation of two new ones, nevertheless there is no death. To speak of the disappearance of the parent cell as an example of death, as some have done, is a mere figurative use of language. There is no death in such a change, because, as Weissmann puts it, there is no corpse. If we consider the two daughter-cells produced by the fusion, we find not only that they are similar morphologically, but that each of them has possibilities of growth and reproduction equal to those shown by the parent form;—there is apparently no reason why such a process should not go on indefinitely. Amœbæ, as we find them under the microscope, show no signs of old age; the daughter-cells are not less capable of reproduction than the parent cell. It is permissible to suppose that if a single amœba were given a favorable environment it would in time produce an infinite number of descendants, each of them possessing in turn the same unlimited possibilities of multiplication. This is precisely the hypothesis which Weissmann makes when he says that living matter is potentially immortal. It is an alternative hypothesis to the one usually adopted, and Weissmann's contribution to the subject comes not so much from his adoption of this view as from the application he makes of it in considering the higher forms of life in which death is an indisputable reality. Weissmann's theory of the origin of death among the metazoa is developed directly from his hypothesis that living matter was originally incapable of natural death. His direct statement that the simplest unicellular forms of life to-day probably retain this primitive constitution of protoplasm has not, however, passed unchallenged. Maupas has made an experimental test of the statement in some very interesting observations. He set himself to observe certain unicellular animals throughout an extended period, when placed under the most favorable conditions for growth and multiplication. The infusoria were chosen for experiment. After making careful observations upon the best conditions of temperature and food, an individual was selected, placed upon a microscopic slide in a suitable moist chamber, and kept under the most favorable conditions possible for propagation. A faithful record was kept each day of the increase in number through multiplication by division of the specimen chosen for study. After the increase had reached some hundreds of individuals, one of them was again isolated and allowed to multiply, and so on until unmistakable signs of what he calls a senile degeneration became apparent in the offspring. His experiments lasted for a variable time. In no case were the observations carried over less than fourteen days, and in the case of stylonichia pustulata, upon which the most careful experiments were made, the successive progeny were cultivated for nearly five months.

The rate of growth in some of the species was incredibly fast. He estimates that in six and one-half days a single stylonichia, at a temperature of 25° to 26° C., might produce by repeated fissions a body of protoplasm weighing one kilogramme, and in thirty days a mass of protoplasm a million times larger than the sun. He was able to observe that after a certain number of generations the progeny began to show signs of a physiological decline. The new animals formed were smaller than normal, seemed weaker, were not so well provided with cilia, and the nuclei contained within them gave microscopical evidence of pathological changes. Maupas looks upon this result as proof of a genuine senility which would have resulted—had the process of isolation been continued sufficiently long—in the natural death of all the descendants, despite the most favorable conditions for living. After a colony began to show signs of old age he found that if one of the animals was taken out and mixed with another lot having a different ancestry, conjugation took place. The weakened infusorian united sexually with one of the more youthful forms, and rejuvenescence was thereby secured. The descendants of this pair multiplied again with the original vigor and gave rise to normal healthy offspring. Weissmann takes exception to these experiments. The infusoria are the most highly developed of the unicellular animals, showing a marked degree of specialization of structure. Furthermore they are known to conjugate at certain periods in their life history. A pair will come together and exchange a portion of their nuclear material, after which

each begins to multiply by simple fission with renewed vigor for a certain undetermined period. It may be that in so highly a differentiated form the primitive reproductive power of protoplasm has been specialized in a particular structure of the cell, as in the higher animals it has been reserved only to the germ-cells; so that in this regard the infusoria might be classed with the metazoa rather than with the protozoa. Moreover, it may be doubted whether Maupas really kept his captive infusoria under perfectly normal conditions. Possibly the experiment could be made with greater certainty of success in this particular by using bacteria. Granting, however, that no exception can be taken to the experiments as made by Maupas, and that his results are correct, Weissmann contends that in the more primitive forms, in which reproduction is always by simple fission and anything approximating sexual conjugation is unknown, his fundamental hypothesis must still be true—death can occur only by accident, and not by natural decay. In the amœbæ, bacteria, and similar forms of life no conjugation has been discovered. While the conditions of life are favorable, growth and multiplication go steadily on. When the conditions of life are unfavorable—*e.g.*, when moisture is withdrawn—forms like the amœba may become encysted and cease to show the properties of living matter until more favorable conditions prevail. Götte has seized upon this process of encystment as the equivalent of death, but we will speak of the theory of this author after Weissmann's theory has been stated.

Let us assume that Weissmann is right in his fundamental hypothesis, and that the first forms of life were potentially immortal, as the simplest forms of life are to-day. What, then, has become of that immortality in organisms like ourselves? What was the origin of death? Weissmann makes the supposition that in the higher animals we have two kinds of living matter, one composing the mass of the body, which unquestionably is subject to a natural death, and one composing the reproductive cells, which is evidently possessed of potential immortality, since if fertilized and kept under proper conditions it will give rise to an infinite number of descendants. The former, the mortal, he speaks of as somatoplasm, the latter, the immortal, as germ-plasm. Furthermore, he supposes that the germ-plasm, constituting the reproductive cells in any individual, is directly derived from the fertilized ovum from which that individual developed. The fertilized ovum is a single cell; by cell division it multiplies a billion-fold and more to make the body. Of this infinite number of cells those which make up the muscles, skin, etc., although directly derived from the ovum, have become specialized physiologically as well as morphologically to fit them for the performance of their special functions, and at the same time they have lost the potential power of immortality which characterized the germ-plasm of the ovum. But among this infinite number of cells there are always certain ones which do not undergo specialization; they remain like the ovum from which they were formed; they retain a portion of the germ-plasm with its powers of immortality, and these cells become the ova and spermatozoa from which new organisms may be developed in turn. If we carry back this conception through the line of ancestral forms from which man has been developed, it involves the idea that the germ-plasm has been actually continuous throughout the history of living things, and that it represents the immortal protoplasm of the unicellular forms from which the metazoa were evolved. This is the doctrine which goes by the name of the "continuity of the germ-plasm," and in the form in which it is presented makes one of the most original contributions given to biology within recent years. The question as we have it before us now may be stated in this way: The unicellular forms are potentially immortal; the many-celled animals contain an immortal germ-plasm and a mortal somatoplasm, and yet the many-celled animals have been directly derived from the unicellular forms. In the first many-celled animals produced, the different cells must have had similar properties; they must all have been equivalent to reproductive cells. But subsequently, after specialization of structure and physiological division of labor had become established, it happened that the vast majority of the cells of the body, all those in fact that had undergone differentiation in structure and function, lost the power of perfect nutrition, and became subject to old age and death. Upon what biological grounds can we explain this variation? Weissmann refers it to the operation of the law of natural selection and states his theory briefly in saying that death is an adaptation, acquired because of its utility to the race on the one hand, and, on the other hand, because, after the beginning of a differentiation in function among the cells, the possession of immortality by all the cells was no longer of any value to the race, and therefore was not brought under the preserving influence of natural selection.

With reference to the first of these reasons, the utility of death to the race, it must be borne in mind that the operation of the law of natural selection is directed entirely toward the perpetuation of the species. Anything that endangers this perpetuity will be discarded, and the duration of life of the individual is a point worth fighting for, or against, only in so far as it influences the struggle for existence of the species. If natural death had not appeared, and creatures could have been destroyed only by fatally adverse changes in their environment, then we may imagine that every species would have been burdened in its fight for existence by individuals whose physical value had been impaired by previous minor accidents, such as loss of limbs, etc. There would have been, from the pitiless stand-point of natural selection, many useless mouths to feed. Weissmann was inclined in his first essays to lay great stress upon this point, but in later years he has emphasized chiefly the second of the reasons given above, namely, that immortality was lost to the non-reproductive cells because, being of no direct value in the perpetuation of the species, they were not acted upon and preserved by natural selection. This tendency of structures to retrograde and disappear when their value to the species becomes *nil*, even though they may not be actively injurious or burdensome, because natural selection no longer acts to preserve them, is something of a new idea in biology. Weissmann attaches great importance to it, and has coined for it the term panmixia. A simple example of its action is seen in the absence of eyes in the cave-inhabiting animals. Many of the crustacea living in the dark caves have lost their eyes—by panmixia, Weissmann would say; that is, in their peculiar environment their eyes are no longer of use, and they have therefore degenerated and disappeared, in the course of generations, by the lack of the direct preservative influence of natural selection. So Weissmann thinks that the original immortality of living matter became lost to the non-reproductive cells in the many-celled animals because, being of no value to the species, indeed, on the contrary, threatening the species with an unnecessary burden, natural selection let it alone.

Many eminent biologists have found a logical difficulty in understanding how from cells originally immortal cells that were mortal could have been derived by differentiation of any kind. They hold that natural selection can only operate upon a structure which exists, it cannot create a thing outright. If living matter was all originally immortal how could natural selection, by negative or positive action, produce mortality, if in some degree this latter property was not already inherent in living matter. As one of the objectors (St. George Mivart) puts it, the difficulty is to understand the first step, the beginning of something from nothing. Objections of this kind are of course fallacious; it is curious that they should have been seriously made by eminent men. The words mortality and immortality do not stand for definite things; they are not substances or entities, or whatever term of this kind one may choose to use. On the contrary, they are in this case merely convenient phrases to express the kind of nutrition going on in living things, whether it is self-perpetuating or self-limiting. They are properties which are connected with the physical or chemical structure of the living molecule, and this latter is a thing

which does exist and may be acted upon and modified by natural selection in many ways.

In accepting or refusing Weissmann's theory of the origin of death, everything seems to depend upon the validity of his fundamental hypothesis with regard to the absence of natural death among the primitive forms of life. If we admit that there are simple organisms, such as the bacteria or amœba, which do not propagate by conjugation or by any method of multiplication other than simple fission, it would seem logically impossible for such a species to be perpetuated unless its protoplasm is exempt from senility. If we do not accept this solution, then we must suppose either that there is some kind of sexual rejuvenation which has not yet been discovered in these particular forms, or that there is some process of molecular rejuvenation occurring at periods in the life-history of such forms which brings the living substance back to its primitive constitution and nutritive vigor. Götte has clearly recognized this necessity, and has proposed a theory which is logically acceptable. According to Götte, death is a necessity immanent in life. As regards the unicellular forms of life, he avoids the difficulty which has just been described by assuming that the process of encystment is the death of the old individual and the beginning of a new one. Encystment, of course, is known to occur among the unicellular forms. During the process the visible evidences of life, such as movement, come to an end, to be renewed again after a certain period, or under more favorable conditions. Götte believes that during the encystment a change of molecular structure takes place. There is first a dissociation or dissolution, which is an actual death, inasmuch as the properties of living matter are lost. This, however, is succeeded by a stage of reconstruction with the formation of new protoplasm possessed of the primitive powers of assimilation, and capable of developing and multiplying for a certain period. This is obviously an hypothesis which it is practically impossible to test by chemical investigations. To the physiologist it will probably not be acceptable on theoretical grounds because of the difficulty of conceiving how matter once in the dead form can again pass into the living form, as the result of spontaneous molecular activities, and without the aid of an exciting or liberating force. Dead matter, as we know it, is converted into the living form only by the process of assimilation on the part of matter already living, whereas the hypothesis of Götte calls upon us to believe that the transition may take place by virtue of the inter-molecular movements in the dead matter itself. Encystment, then, according to the theory of Götte, represents at the same time the primitive form of natural death and the primitive method of reproduction. As the metazoa have been derived from the unicellular forms, he further assumes that among the former both natural death and reproduction have been acquired by direct inheritance. As in the protozoa reproduction and death stand in a causal relationship, so in the simpler forms of metazoa, *e.g.*, in the orthonectidæ, this connection is still maintained, inasmuch as the liberation of the ova results in the death of the individual. Among the higher forms the relationship between reproduction and death is not so evident, though the theory demands always a causal connection between the two processes.

It will be evident from this brief statement of Götte's views that he differs from Weissmann, not only in his belief of the necessity and universality of death, but also in respect of the discontinuity of life. Among the protozoa, which propagate by encystment, his theory denies that the new individual is directly sprung from the living substance of the parent cell. On the other hand, the general belief has been that in some way the continuity of life is maintained. Darwin's theory of pangenesis, which was formulated to explain the phenomena of heredity, implies a continuity of living matter between parent and child. It will be remembered that in this theory the ova and spermatozoa are supposed to contain minute germs, gemmules, thrown off from the different cells of the body and collected in the germ-cells. Under the proper physiological stimulation, the gemmules develop into organs like those from which they were derived. The gemmules must be considered as living matter; hence the theory implies a direct carrying over of living substance from parent to child, a continuity of living matter at least. In contrast with this the theory of Weissmann supposes a direct continuity of germ-plasm, the essential part of the germ-cells of the child being an actual portion of the germ-protoplasm of the reproductive cells of the parents. The immortality of the germ-plasm and the direct continuity of the germ-plasm, are, then, the fundamental parts of Weissmann's theory, and his hypothesis of the origin of death as regards the somatoplasm follows naturally if we accept these premises. It will be observed, however, that Darwin's pangenesis theory may also be considered as implying the essential immortality of the material composing the germ-cells, although neither Darwin himself nor those who have made use of his theory have ever made a specific statement of this kind.

In the older treatises upon the nature of death a distinction was often made between molecular death and somatic death. The former term was meant to include those changes of disassimilation or katabolism, to use a more modern word, which are supposed to be in play in every bit of living matter, and to lead to the formation of dead waste material, such as urea, carbon dioxide, and water. Somatic death was used, as it is at the present time, to describe the final cessation of all vital activities in the body at large. It was supposed that we had here the production of dead from living matter by two entirely different methods. The term molecular death is obviously an unhappy one, and has fallen into disuse, although it is possible that it is an accurate statement of what takes place. The essential nature of the physiological oxidations which lead to the formation of the products of disassimilation is at present a subject of discussion, and will probably remain so for a long time. Treating the subject in the most general way, it seems evident that in disassimilation one of two things may take place. If, for the sake of simplicity, we confine our attention to a single cell, then it is possible, on the one hand, that the formation of the wastes of nutrition is brought about by the actual death and disintegration of portions of the cytoplasm, their places being supplied by new living material formed in other parts of the cytoplasm or in the nucleoplasm. Or, on the other hand, it is equally possible that in normal disassimilation no single living molecule undergoes total destruction. The process of dissociation may be such that only a portion of the molecule is split off, and lost from the cell as dead material, while the remainder of the molecule reconstructs itself from the food material of the cell-juices into the originally complex molecule of living matter. This, in fact, is the hypothesis of physiological oxidation which has been proposed by Pflüger with special reference to the metabolisms of muscle during functional activity. His theoretical views have much to recommend them, and some account of them is usually given in the text-books of physiology.

W. H. Howell.

DERMATOL, the trade name for the subgallate of bismuth, $BiC_7H_7O_7$, containing fifty-five per cent. of the oxide of bismuth. It is a fine, yellow powder, devoid of odor, quite insoluble in water or any of the ordinary solvents, free from irritating action, and non-poisonous.

It has been introduced to replace iodoform, on account of its freedom from many of the disagreeable qualities of that drug.

It is not a bactericide, but prevents their growth or formation, and in this way compares favorably with iodoform and aristol. Its beneficial action is due to its neutralizing the ptomaïnes produced. It is not only insoluble but also repels water, thus rendering the part unfavorable to the growth of bacteria.

It is not so suited to the treatment of sloughing or septic wounds as iodoform, nor is it sufficiently stimulating in chronic indolent ulcers. It is most serviceable to promote cicatrization in healing surfaces, and in affections of the skin; in burns, scalds, chancres, eczema, particularly when characterized by much discharge, it has been used with marked success. In these cases the parts become dry on the second or third day of its use, and the relief is very marked. If the part is previously washed with an antiseptic lotion its action is greatly assisted. It may be applied by dusting on the part, or in the form of an ointment of one part in ten. It may with advantage replace oxide of zinc, starch, etc., as a dusting powder in scalded and denuded surfaces.

In doses of thirty to ninety grains it has been given internally, as a substitute for the subnitrate, for diarrhœa in children, in phthisis, typhoid, etc., with good results. It may be given in wafers or as an emulsion.

Beaumont Small.

DIARRHŒA. If we are to credit the results of recent investigations, the symptoms and pathological conditions of diarrhœa, to a larger degree than we have supposed heretofore, are due to the products of bacterial action in the alimentary canal. It has been shown, almost conclusively, that ptomaïnes develop in the intestines during the decomposition of food in diarrhœa, as well as sometimes in the opposite condition of constipation, and the results of treatment show that in diarrhœal states those medicaments are most useful which exercise a repressive, if not a destructive action upon bacterial growth.

Numerous cases of obstinate constipation with anæmia and slight toxic symptoms have been promptly relieved by a free evacuation of the alimentary canal, and by the exhibition of antiseptic remedies like preparations of mercury, bismuth, and naphthol, strongly suggesting that some leucomaïne poison must have been produced in the intestine, or cast into it, which, being absorbed, caused the mischief, and of which the constipation prevented the regular discharge. Cases of diarrhœa are not only benefited by germicide medicines taken by the mouth, but also by similar remedies introduced in the form of large enemas.

In the treatment of diarrhœa the necessity of insuring perfect digestion of such food as is taken, and of keeping the intestinal canal free from abnormal decompositions, has been of late very much emphasized, and what we ought always to have understood is being recognized more than ever, that every particle of food taken that is not digested is a menace to the intestinal mucous membrane by the irritation its decomposition may light up.

It should be a positive condition in the treatment of all cases, especially of the more chronic forms, of diarrhœa, to obviate that sort of indigestion or disorder; and it is coming also to be recognized that such cases cannot be treated by an occasional dose of medicine, regardless of conditions and circumstances, but that the patient must be put upon a strict regimen, and that he cannot vary from it in any particular, or lose his courage or watchfulness of himself for a day, without danger of a relapse.

In the chronic cases the digestion may be conserved by various gastric and other tonics in small doses, and by peptogenic preparations, and by a most careful selection and preparation of food.

The normal condition of freedom from vicious decompositions in the intestinal canal may be conserved by moderate doses of salicylate of bismuth (2 to 5 grs.), subnitrate of bismuth (5 to 10 grs.), hydronaphthol or betanaphthol, which may be taken in doses of 5 to 20 grains, or even more, without harm, calomel ($\frac{1}{20}$ to $\frac{1}{30}$ gr.), biniodide of mercury ($\frac{1}{30}$ to $\frac{1}{60}$ gr.), or bichloride of mercury ($\frac{1}{60}$ gr.), and by salol (1 to 3 grs.), but the possible unpleasant effect of the last upon the kidneys when given in large amount should lead to caution in its use. Arsenite of copper has been highly praised of late for diarrhœa, mostly for the acute forms, in very minute doses ($\frac{1}{200}$ to $\frac{1}{100}$ gr.), frequently repeated. It is a drug of superior value, both in the acute and chronic forms, and may be taken in somewhat larger doses than those mentioned above. There would seem to be no objection to using it in small doses regularly for a long time in those cases of debility which show a tendency to diarrhœa from even the smallest variation from the usual dietary or hygienic conditions; for then its wholesome effect on the intestinal canal would be a sustained one, and the general tonic effect of the arsenic would be experienced.

It has been discovered recently that a form of amœba (amœba coli) swarms in the intestinal canal at times and causes dysentery of such a character that it is liable to be mistaken for one of the forms of diarrhœa described in the original article on this subject in Vol. II. The dejections are liable to much variety in their character, and the diarrhœa to alternate with constipation. The sanguineous and mucoid qualities of the discharges are less marked than in ordinary dysentery, although blood and thick mucus may freely appear at times. The disease lasts long and is very intractable to treatment, and the mortality is high. It is remarkably prone to produce complications, especially perforation, peritonitis, abscess of the liver, and, consecutive to it, of the lung. Fever is not a marked symptom in the disease when uncomplicated. Ulceration of the intestinal wall occurs in all bad cases, —deep excavations and underminings, but with little true suppuration. The amœbæ can easily be found in the discharges, and, of course, are the sole diagnostic sign. Their discovery in small numbers in the stools in any case would not absolutely prove that they were the cause of a diarrhœa, since they are sometimes discovered in the dejections of health. As a matter of fact, in these cases, the amœbæ swarm in the stools, as well as in the products of the abscesses of the liver and of the lung.

Injections of substances destructive to the parasites seem the most useful treatment. Their complete destruction in the walls of the intestines is evidently difficult, owing to the unavoidable obstacles to carrying effective quantities of the medicament to every nidus of their multiplication in the irregularities of the intestinal lining, as well as in the ulcers and excavations.

The treatment of many of the more chronic forms of diarrhœa by enteroclysis, or injections of sterilized water containing various medicaments, is very properly coming more into vogue. A salt solution, of 6 or 7 parts of chloride of sodium to the 1,000 of water, is best for irrigation, and weak solutions of tannic acid (1 to 3 drachms to the quart) or boric acid, for destruction or repression of micro-organisms, work best. For any ordinary case of diarrhœa it is unsafe to use corrosive sublimate or carbolic acid solutions; they are too poisonous, whereas the tannic and boric acids, in proper quantities, are quite harmless, as is also hydronaphthol, which may be used in a saturated solution. Occasionally a slight admixture of some opiate is required, but ought never to be used unless demanded by pain or irritation of some sort.

This method of medication is not by any means as difficult to use as it would seem, since almost an unlimited amount of water can easily be introduced into the bowel, provided the patient is horizontal, and the movement of the water into the body is extremely slow, and the stream perfectly continuous from a fountain syringe, the reservoir of which is elevated but a few inches. No pulsating stream will do; the water must be, when it reaches the intestine, as warm as the body, and may be two degrees above the normal heat; it must be at least four degrees above normal body heat as it leaves the bag. If

too much is introduced for the large intestine to contain, it readily passes the ileocæcal valve into the small intestine, and, if further relief is required, into the stomach and out through the mouth. With the precautions named, all the tenesmus disappears, and even little children receive the treatment without complaint. But slowness of introduction of the water is a precaution never to be forgotten.

The method has several distinct advantages: it washes the intestines free of mucus and decomposing and decomposed substances of numerous kinds; it washes away vast myriads of microbes, which may be wholly or in part responsible for keeping up the diarrhœa, if not of causing it originally; and it kills or lessens the growth and virulence of swarms of them that remain. In dysentery, especially, a treatment of this sort is in the highest degree useful when practised once or twice each day, particularly when the tannic acid is used; only, to be most effective, it should be often repeated, or, better still, employed as an irrigation with a long double tube, having a large and free outflow. This procedure should be carried out once or twice each day.

The treatment, moreover, is a rational application of the principles so effective on other parts of the body, namely, a thorough cleansing of inflamed surfaces, the removal from them of substances, however produced, which are capable of causing irritation, and the soothing of them by appropriate medicines.

There is perhaps no form of diarrhœa where the carrying out of these principles is more demanded than in the summer diarrhœas of children, often improperly called cholera infantum, and in these this treatment deserves a freer trial. But in this class of patients it is specially important that the treatment be carried out with care, caution, and faithfulness. It unavoidably requires the hand of the physician or of a most carefully instructed nurse.

The frequency of the injections should depend on the effect. The effect of each one should be to quiet the irritation for a number of hours, and during this time the bowel should remain unmolested, the treatment being repeated on a recurrence of the symptoms.

No attempt should ever be made to pass a tube through the sigmoid flexure. The effort is rarely successful, and the danger from the use of a hard tube is great.

Norman Bridge.

DIEPPE. A fashionable watering-place, and one of the favorite sea-side resorts of the Parisian "monde." It is prettily situated on the coast of Normandy, at the mouth of the river d'Orques, and between high calcareous cliffs. The bathing season lasts from June to September. To quote from Baughan ("The Northern Watering-Places of France"): "The life of the place seems concentrated on the beach, and at the *Établissement des Bains de Mer*. The beach is quite a mile long, and extends from the timber-yards near the jetty to the foot of the high cliff on which stands the Château, a picturesque old building with a square tower, now used as a barrack. The beach at Dieppe was once but a stretch of meadow-land, but now it is a fine promenade, laid out as an English garden, and bordered by stately hotels. Trees would be an improvement, but of these there are none, which is a pity, for the heat at noontide along the unshaded promenade is something not to be endured. There is a wide and beautiful expanse of sea at Dieppe, and though the beach at high tide is of bowlders, when the sea goes out there are sands, but the bathing at high tide is, of course, on the bowlders, and this is one of the greatest disadvantages of Dieppe.

"The Casino and the Établissement des Bains de Mer are the property of the town, and they are charmingly managed. They are to the southwest of the beach—just beneath the cliff on which stands the Château. The Établissement is built in imitation of the Crystal Palace, London, and contains a theatre and ball-room, several charming salons, a billiard-room, and a reading-room. It is surrounded by a well-laid-out garden, where there is a place set apart for children's sports, a gymnasium, and several pavilions where different games are played."

Accommodation.—The principal hotels are the Royal, l'Hôtel de Bristol, le Grand Hôtel des Bains, l'Hôtel de la Plage, and le Grand Hôtel de Dieppe. All these hotels are situated along the beach, and are expensive. L'Hôtel du Nord, Quai Henri IV.; l'Hôtel de la Paix, Grande Rue; and l'Hôtel du Géant, Rue de Chêne-Percé, are more moderate.

Numerous interesting excursions can be made into the surrounding country. Of late years many English and American visitors are seen at Dieppe.

Edmund C. Wendt.

DIGESTION. The changes and additions now contributed to the articles furnished by the writer to the subject of "Digestion," the "Digestive Secretions," etc., are rendered necessary, in part, by the increase in our knowledge from new observations and experiments, but still more owing to an alteration in the point of view that must, sooner or later, work great, if not radical, changes in the whole of physiology.

It is now being perceived that it is impossible to explain vital processes entirely by the laws of physics and chemistry. The attempt to do so has led physiologists aside from the true path, and we are now obliged to confess failure and seek other ways.

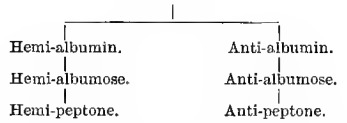
There is also a hopeful broadening taking place; and it is not so common as it was to assume that, what holds for one animal applies to others, even though alike in many respects. Greater caution and breadth, and a truer insight, with less hasty generalization, will probably mark the physiology of the future.

This has been very clearly illustrated by the views recently published on the subject of digestion, as the writer will endeavor to show.

It would seem that we have been too ready to accept simple explanations, and to consider life processes as much less complicated than more recent investigations show them to be.

Proteid Digestion.—It is still held that in peptic digestion, peptone, or more properly peptones, are the final products of the action of gastric juice on proteids; and that the process of digestion is one of hydration; but between albumin on the one hand and peptones on the other, there are now recognized several bodies of distinct properties.

The following tabular statement embodies the most recent views, and indicates the antecedents of the final peptones:



Hemi-peptone may, by the pancreatic secretion, be split up into leucine, tyrosin, etc., but this is not true of anti-peptone.

Albumoses may be classified chemically, according to the action on them of different reagents, thus:

1. *Proto-albumose.*—Soluble in cold and hot water, and in dilute saline solutions; precipitated by saturation with magnesium sulphate or sodium chloride.

2. *Hetero-albumose.*—Insoluble in water; soluble in cold solutions of sodium chloride of a strength of from one-half to fifteen per cent.; precipitated by heating to 65° C., the coagulum being soluble in dilute acids and alkalies. It is precipitated by alcohol, but, unlike other albumoses, is thus altered to an insoluble body, dysalbumose. Like the preceding, it is precipitated by saturation with neutral salts.

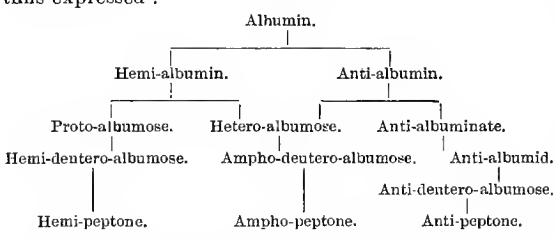
3. *Deutero-albumose.*—Soluble in cold and hot water; not precipitated by saturation with sodium chloride or magnesium sulphate, but thrown down by saturation with ammonium sulphate.

It is in its reactions allied to the peptones, for it is not precipitated by copper sulphate, and only gives the nitric acid reaction in the presence of excess of salts.

Variety of proteid.	Hot and cold water.	Hot and cold saline solution, *e.g.*, 10 per cent. Na Cl.	Saturation with Na Cl or Mg SO_4.	Saturation with Am_2 SO_4.	Nitric acid.	Copper sulphate.	Copper sulphate and ammonia.	Copper sulphate and caustic soda or potash.
Albumins.	Soluble in cold, coagulated in hot, water.	Soluble in cold, coagulated in hot, solutions.	Not precipitated.	Precipitated.	Precipitated in cold, not soluble on heating or only slightly.	Precipitated.	Blue solution.	Violet solution.
Globulins.	Not soluble in either.	The same as albumins.	Precipitated.	Precipitated.	The same as albumins.	The same as albumins.	The same as albumins.	The same as albumins.
Proto-albumose.	Soluble in both.	Soluble in both.	Precipitated.	Precipitated.	Precipitated in cold; precipitate dissolves with heat and reappears on cooling.	Precipitated.	Violet solution.	Rose-red solution.
Hetero-albumose.	Insoluble, *i.e.*, like globulins, precipitable by dialysis from saline solutions.	Soluble in both; partly precipitated, but not coagulated on heating to 65° C.	Precipitated.	Precipitated.	Precipitated in cold; precipitate dissolved with heat and reappears on cooling.	Precipitated.	Violet solution.	Rose-red solution.
Deutero-albumose.	Soluble.	Soluble.	Not precipitated.	Precipitated.	This reaction only occurs in presence of excess of salt.	Not precipitated.	Violet solution.	Rose-red solution.
Peptone.	Soluble.	Soluble.	Not precipitated.	Not precipitated.	Not precipitated.	Not precipitated.	Violet solution.	Rose-red solution.

The above table, from Halliburtin's "Chemical Physiology and Pathology," puts the most recent information in a compact form.

According to Neumeister, the relations of the various proteid bodies formed in the digestive process may be thus expressed :



From the above table it appears that albumin is made up of hemi-albumin and anti-albumin, and the subsequent changes of each are indicated down to the final products in peptones, and all are to be regarded as stages in a hydration process.

Primary albumoses are those formed directly from albumin, *i.e.*, proto-albumose and hetero-albumose. Although this table shows that digestion is now regarded as a much more complex process than formerly, it seems to the writer that what we have ascertained is rather an indication of possibilities than actualities, and that our views may be expected to undergo great changes, if they are not shown to be wholly inadequate. It is also likely that the process of digestion of proteids may vary much for individuals, or even in the same individual at different times, not to mention differences for unlike groups of animals. But certain it is, that a modest and expectant attitude, in view of the radical modifications that have recently taken place in our ideas with regard to this subject, is the only correct one.

Besides, it is more and more apparent that conclusions founded on artificial or laboratory digestion are to be drawn with the greatest care.

Digestion of Fat.—Owing to the more rational view now taken with regard to digestion generally, and with regard to the true nature of absorption, the digestion of fat is more readily comprehensible, though no very new light has been thrown on the action of those digestive juices that are concerned in altering the ingested fat.

Though the pancreatic juice, especially when mixed with bile, has the power of splitting up neutral fats into fatty acids and glycerine, from which result a certain proportion of soaps, yet there is reason to believe that the greater part of the fat finds its way into the blood as a very fine emulsion, or even as "molecular fat."

The fact that, even in the absence of bile or pancreatic juice, some fat digestion may, if not at first, eventually take place in an animal, shows that we have been regarding digestion too much in a purely chemical light.

Bile.—The tendency, in view of recent researches, is rather to confirm the opinions of those that held that the bile itself takes no essential part in digestion, though helpful to the pancreatic juice; at the same time it must be said that a conservative attitude is the most justifiable one at present.

Fæces.—Though actual experiment has not recently brought to light much that is new in regard to the composition of fæces, it is still clear to the writer's mind that the facts of clinical medicine indicate that many harmful products are in all probability discharged from the body by means of the intestines. In other words, we must regard the intestine as a great excreting as well as secreting surface, and must believe that the fæces contain not only some of the altered digestive secretions and the indigestible remnants of the food, but possibly numerous products of tissue-waste, either as they were formed in the cells of the various tissues, or as they were modified by the glandular and possibly other cells of the gut.

A subject of which some notice may be taken is self-digestion of the stomach, etc. This is all the more necessary as the views that formerly prevailed indicate how much was overlooked. In this connection the writer begs leave to introduce an extract from his "Animal Physiology" (D. Appleton & Co., New York, 1889).

"*Self-Digestion of the Digestive Organs.*—It has been found, both in man and other mammals, that when death follows in a healthy subject while gastric digestion is in active progress and the body is kept warm, a part of the stomach itself, and often adjacent organs, are digested, and the question is constantly being raised, Why does not the stomach digest itself during life? To this it has been answered that the gastric juice is constantly being neutralized by the alkaline blood; and, again, that the very vitality of a tissue gives it the necessary resisting powers, a view contradicted by an experiment which is conclusive. If the legs of a living frog be allowed to hang against the inner walls of the stomach of a mammal, when gastric digestion is going on, they will be digested.

"The first view (the alkalinity of the blood) would

not suffice to explain why the pancreas, the secretion of which acts best in an alkaline medium, should not be digested.

"It seems to us there is a good deal of misconception about the facts of the case. Observation on St. Martin shows that the secretion of gastric juice runs parallel with the need of it, as dependent on the introduction of food, its quantity, quality, etc. Now, there can be little doubt that, if the stomach were abundantly bathed, when empty, with a large quantity of its own acid secretion, it would suffer to some extent at least. But this is never the case; the juice is carried off and mixed with the food. This food is in constant motion, and doubtless the inner portions of the cells—which may be regarded as the discharging region, the outer, next the blood-capillaries, being the chief manufacturing region of the digestive ferment—are frequently renewed.

"Such considerations, though they seem to have been somewhat left out of the case, do not go to the bottom of the matter. Amœba and kindred organisms do not digest themselves. Some believe that the little pulsatile vacuoles of the infusorians are a sort of temporary digestive cavities.

"But, to one who sees in the light of evolution, it must be clear that a structure could not have been evolved that would be self-destructive.

"The difficulty here is that which lies at the very basis of all life. We might ask, Why do living things live, since they are constantly threatened with destruction from within as from without? Why do not the liver, kidney, and other glands that secrete noxious substances, poison themselves? We cannot in detail explain these things; but we wish to make it clear that the difficulty as regards the stomach is not peculiar to that gland, and that even from the ordinary point of view it has been exaggerated."

The Movements of the Alimentary Tract and the Nervous Mechanisms Concerned.—So far as the movements of the tract are concerned, we find a localization of function with an interdependence corresponding to anatomical differentiations. The movements of the œsophagus and stomach, for example, are more independent than those of the rest of the digestive canal. Peristalsis naturally takes place in the region lying between the stomach and the cæcum, while the large gut, and especially the sigmoid flexure of the colon and the rectum, have a subordinate degree of independence in this respect.

The nervous supply is more or less distinct in those regions of greatest localization of movement. Nevertheless we recognize both in health and in disease, even in such parts as the small intestine, that there is a tendency for the peristalsis to be confined to one region, temporarily in health, but for a protracted period of time in disease, as in colic.

There is little new to add to what appeared in the original article on the movements of the œsophagus or the nerves concerned, and we have still a great deal to learn about the innervation of the stomach.

Gaskell, acting on the suggestion furnished by the double nerve-supply of the heart, has projected a scheme for the sympathetic system which, as applied to the alimentary canal, has already yielded some definite results, and it seems probable that it will be shown that there is to this long muscular tube, as to the less obviously similarly formed organ the heart (tubular in embryonic life and also derived from the mesoblast), a double nervous supply of motor or augmenter and inhibitory fibres.

The more we learn of the vagus, the more wonderful a nervous path does it appear to be. It contains both afferent and efferent fibres for the alimentary canal, fibres which seem to be continued through nerves bearing other names, as the splanchnic, to a very wide distribution.

Fig. 151 gives in a highly diagrammatic form the most recently known facts regarding the innervation of the alimentary tract. Physiologists are not yet thoroughly agreed as to the true nature of the intestinal movements. The fact that they will take place in an isolated loop of intestine, that they are augmented by conditions producing an increase in waste products, notably carbon dioxide, as in asphyxia, suggest that they may be independent of the central nervous system, yet usually more or less under its control.

The functions of the ganglia in the intestinal walls are no more known than are those in the heart. Nevertheless, the writer is inclined to believe that it will ultimately be considered that nearly all functions are in a sense reflex, *i.e.*, dependent on stimuli reaching a centre and determining the nature of the outgoing impulses. But in this there are all degrees. The cardiac and intestinal movements are so readily induced in any case that their essentially reflex character may not be so obvious; and it is not surprising that some have been

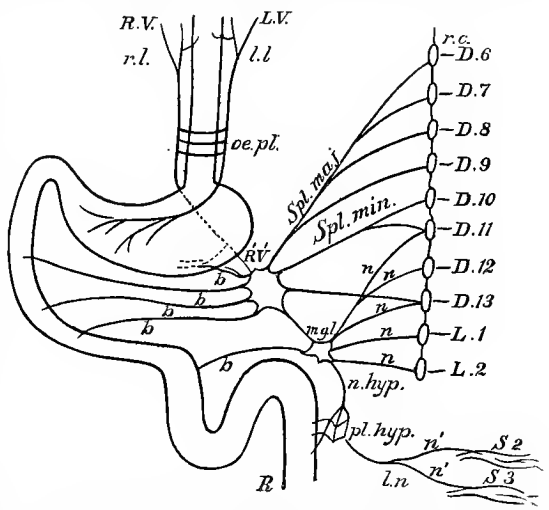


Fig. 151.—The whole is purely diagrammatic, which renders the comprehension of the general plan simpler. *L. V.*, left vagus, passing to the anterior aspect of the stomach; *R. V.*, right vagus, communicating with left vagus in œsophageal plexus, *œ. pl.*, and supplying the posterior part of stomach, then continued (*R' V'*) to solar plexus, represented by a single ganglion, and connected with the inferior mesenteric ganglion (plexus), *m. gl.*; branches from solar plexus to stomach and small intestine, and from mesenteric ganglion to large intestine, represented by *b*; *Spl. maj.*, large splanchnic nerve from thoracic ganglia, and *r. c.*, rami communicantes from sixth to tenth dorsal; *Spl. min.*, small splanchnic nerve arising in like manner from tenth and eleventh dorsal nerves (these both join the solar plexus and thence make their way to the digestive tract); *n*, nerves from the ganglia, etc., belonging to tenth, twelfth, and thirteenth dorsal and first and second lumbar nerves, reaching the inferior mesenteric ganglia (plexus) and thence proceeding by the hypogastric nerves, *n. hyp.*, and hypogastric plexus, *pl. hyp.*, to the circular muscles of the rectum; *n'*, nerves from the second and third dorsal nerves (*S2*, *S3*, *nervi erigentes*), reaching the longitudinal muscles of the rectum by the hypogastric plexus. (Modified from Foster.)

inclined to hold to an independence of rhythm that is not natural but peculiar to the laboratory. At the same time they are not reflex in the same sense or degree as the movements of striped muscle may be. Experiments seem to show that in the vagus are found augmenter (motor) fibres for the intestine, and in the splanchnic both major and minor inhibitory fibres, since stimulation of the former causes movements of the gut, and of the latter, arrest of the same.

It is certain that the splanchnic nerves are the paths of vaso-constrictor (augmenter) impulses to the blood-vessels of the gut, and probable that dilator (inhibitory) fibres are found in the vagus, which would correspond somewhat to the cardiac innervation.

As regards the rectum, we are in possession of more definite knowledge. So far as the dog is concerned, and it is not likely that there is any essential difference for man, the longitudinal fibres of the rectum are under the control of fibres which are found in the anterior roots of the second and third sacral nerves (Fig. 151, *S2*, *S3*) and pass along the *nervi erigentes* to the hypogastric plexus (*pl. hyp.*), and so reach the lower gut. Stimulation of

these nerves leads to contraction that pulls down the rectum, owing to the action of the longitudinal muscular fibres.

The supply to the circular fibres is derived from nerves which leave the spinal cord by the lower dorsal and upper lumbar (Fig. 151) nerves, and pass to the rectum by the inferior mesenteric ganglia, the hypogastric nerves, and hypogastric plexus (*m. gl., n. hyp., pl. hyp.*). The fibres lose their medullary sheath before reaching the gut. Stimulation of this set leads to contraction of the circular fibres only, and results in the contents of the gut being squeezed out.

As is well known, disease of the central nervous system is apt to be followed by obstinate constipation, so that it seems clear that the sigmoid flexure of the colon and the rectum, at all events, are governed by a reflex mechanism. It is likely that a similar mechanism will eventually be shown to exist for the small intestine, and possibly the stomach.

The Removal of Altered Products from the Alimentary Canal, or Absorption.—The final products of digestion, as this term is commonly understood, are peptones, sugar, and emulsified fats, principally. Till recently it has been customary to teach that peptone was absorbed by the capillaries, and passed as such into the blood-stream; that sugar disappeared in the same manner; and that the work of the villi—at all events of their columnar cells and structures other than the blood-vessels—was largely confined to the removal of fat.

There was always a great difficulty in showing the presence of peptone in the blood-stream at all, even when digestion was in full progress; while more recent researches have made it clear that the injection of peptone, the product of artificial digestion, results in undoubted poisoning.

According to some investigators, peptone and albumoses are absent from blood and lymph during even the most active digestion.

This brings us to consider the real nature of so-called absorption. It has all along, till very recently, been assumed that "animal membranes," in which the intestine was included, acted very much as a piece of parchment, and that osmosis was the great force that determined absorption.

Certain experiments showing changes in peptone when placed in contact with the walls of an isolated loop of intestine, or even pieces of the mucous membrane, tended to shake the older views.

Recently, however, the whole subject of absorption has undergone a revision.

Not to mention the fact that certain salts and other bodies disappear from the intestine at a rate altogether different from what would be expected from their osmotic equivalent, peptone itself is found to leave the living gut much faster than through any diffusive septum.

For an account of experiments bearing on this subject which is easily accessible, the reader is referred to the outline of Dr. Weymouth Reed's researches, published in the *British Medical Journal* for February 13 and May 28, 1892. (See also *Journal of Physiology*, vol. xi., p. 312.) Dr. Reed in the first series of experiments used frog's skin, and showed that the rate of transfer of fluid through the living skin was not in accordance with the laws of osmosis.

Later, he showed that the mucous membrane of the intestine of a rabbit killed during full digestion, when exsected, does act differently from a diffusive septum; *i.e.*, even the removal of a saline fluid does not follow ordinary physical laws, or, in other words, it is a vital process.

The absorption of the fat and the functions of the villi are questions still under discussion. The "striated border" of the columnar cells has always been regarded as playing some important *rôle* in absorption, though exactly what, was not and is not yet known. Heidenhain, in some elaborate researches on the whole subject of the structure and functions of the intestinal mucous membrane (*Pflüger's Archiv*, Bd. xliii., Suppl. Heft) concludes that this striated border is made up of rods set vertically to the plane of the mucous membrane, and a homogeneous substance between them, and that either the one or the other may be withdrawn within the cell. Nevertheless the meaning of the striated border functionally has not been made clearer. There is still difference of opinion as to the part leucocytes play in the absorption of fats.

The writer believes that he was the first to teach dissent from the ordinary views on the subject of digestion and absorption, and to give expression to this in print. (See "Animal Physiology," chapter on the "Removal of Digested Products from the Alimentary Canal," etc.; "The Blood and Blood-vessels in Health and Disease," *New York Medical Journal*, September 13, 1890.)

Briefly, the views the author has held for some six years are these: The laws of physics and chemistry as ordinarily understood will not explain vital phenomena. In seeking for explanations of physiological processes we must bear in mind the course of evolution in animals and the embryological development of the organism. Accordingly, it is not possible to conceive of osmosis, etc., as an explanation of any vital phenomenon. The only solution that is in accordance with facts, is that the capillaries are not merely channels for blood, but are real constructive, ingestive, and secreting mechanisms (glands), and are such in the alimentary tract as well as elsewhere. In explaining digestion in mammals we must not forget the nature of the process in lower forms, even in amœba itself. Intra-cellular digestion, well illustrated in the invertebrates (amœba, hydra, etc.), probably exists in some degree in all animals. Taking this view, the digestion of fats and the absorption of fats become more readily comprehensible. If the capillaries are glands, if their cells be considered as not devoid of living properties, we can understand that they may convert peptones into something else, and so of all the cells that make up the alimentary tract. It is likely that we have hitherto not only been artificial in our views of the nature of digestion and absorption, but have in our conceptions restricted the work far too much both as regards the cells actually involved and the nature of the processes they perform. They do secrete fluids that are digestive, but they or other cells may also cause changes of products within themselves as in the invertebrate series of animals. It is infinitely better to be satisfied with views that are somewhat vague and general than with others more definite, but narrow and out of harmony with the great fundamental conceptions of modern biology. Time and patient research will remedy the former, because we are in this case on the right track, but having started wrong, we may continue so, as indeed we have for long enough, and with great detriment to practical medicine as well as to physiological science.

Since these views were taught by the writer a great change has come over physiology in this very quarter, though it has not extended equally to other departments. The leading English writers on physiology are embodying such views in the latest editions of their works.

As the writer years ago suggested, it would probably be well if we were to discard the term "absorption," at all events as applied to the digestive tract.

"Digestion waits on appetite," *i.e.*, the work of the alimentary canal is largely dependent on the condition of the tissues generally, a truth that it was quite impossible to harmonize in any broad way with the older views of digestion and absorption, but plain enough in the light of what physiologists are now beginning to perceive. After all, in so complicated a process as digestion, "experiments" can only go a certain distance. They are a guide, and tend to confirm rather than to "demonstrate," a term that has been somewhat misleading in physiology.

Summary.—Digestion in mammals is made up of a series of processes, part of which result in fluids being poured out which produce chemical changes in foodstuffs which are more complicated than was once supposed, as has been proved in the case of proteids; followed by other changes, which are intra-cellular and largely unknown in their exact nature, but generally

comprehensible in the light of evolution and embryology, and by bearing in mind that the processes and tissues of the body are related, and in higher animals are under the dominion of the nervous system. Digestion and absorption cannot be separated by any sharp line of demarcation.

That starches are converted into sugar, proteids into peptone, fat emulsified and saponified, are truths so far as they go, but probably take us but a little way into the real nature of digestion.

An abundant blood-supply is a usual accompaniment of the act of secretion, but is not absolutely essential to it.

The whole process of digestion is under the control of the nervous system in the higher animals, including man, in the action of which we must largely recognize reflex processes.

The whole process of the final elaboration of food (absorption) is better understood by remembering the nature of intra-cellular digestion in unicellular and the simpler multicellular animals, and the true nature of capillaries and the cells of which they are composed, and by avoiding conceptions that tend to narrow the work of nature down to the limits of the laboratory. *T. Wesley Mills.*

DIGESTION, DISORDERS OF. Within the past few years some advance has been made in the study of disorders of digestion due to faulty action of the stomach, through the use of the stomach-tube. The methods to be referred to are not to be advised in all, and probably not in the majority of, cases of dyspepsia, because, 1, they are often unnecessary ; 2, they are disagreeable to the patient ; 3, they are (very rarely) dangerous from the possibility of (*a*) injury to the stomach in case of an unsuspected ulceration ; (*b*) inhalation pneumonia from a sudden retching with the œsophageal tube *in situ*, causing food to be drawn into the trachea ; and (*c*) death from the actual nervous shock of this seemingly trivial operation.

Moreover, these methods of examination involve much time and labor for the physician, so that they have not come into general employment, and are at present probably practised chiefly in hospitals where plenty of trained assistants are available. But all these reasons are insufficient to warrant the omission of such examinations in obscure cases which have resisted other clinical study. It is only as conjoined with the clinical evidence that these chemico-physiological researches are to be taken as evidence, for, as has often been said, " the stomach is not a test-tube."

Unfortunately, as in so many other fields of medicine, the therapeutic results of these newer methods of research have as yet been incommensurate with their scientific interest.

The mechanical means for becoming acquainted with the contents of the stomach is a soft, flexible-rubber tube or catheter, twenty-five to thirty inches in length, having bevelled eyelets. It is introduced into the pharynx, either simply warmed or lubricated with warm milk, and " fed " to the patient as the latter goes through the motion of deglutition. Care must be taken that it be introduced so that its end reaches below the level of the fluid to be withdrawn, and that it be not pushed in so far as to curl up and bring its extremity again above the surface of the liquid.

The tube introduced, the stomach-contents are removed either by expression, aided perhaps by cough, or by aspiration. The fluid, which should be a half-ounce or more in quantity, is filtered, and reserved for further chemical examination. With this object in view the time of obtaining the specimen is important. Some authorities, notably Ewald, favor a small " test breakfast," consisting of a two-ounce roll and ten ounces of water or green tea, the tube to be passed one hour after the meal ; others, following Leube, believe that a more generous meal is necessary to call out the full digestive capacity, and advise a meal of twelve ounces of soup, two ounces of scraped beef, and about as much bread, the specimen to be withdrawn in four hours.

The fluid thus obtained may be subjected to the following tests :

1. *For Digestive Power.*—By putting the stomach fluid in a test-tube at the temperature of 99° F., adding a quantity of shredded egg-albumin, and noting the period of completed digestion ; this test may be controlled by others in which the fluid is acidulated with HCl, and by other tests with presumably normal gastric juice, the quantities of albumin used being constant. This is a test of the pepsine strength of the fluid, but it is practically found that the pepsine and other ferments have a pretty constant relation to the HCl strength, so that especial attention is directed to the latter constituent, which is more capable of exact determination.

2. *For General Acidity.*—To be tested by litmus or Congo red paper. This does not distinguish between the different kinds of acids, whether HCl or lactic, but if the Congo paper, for instance, is turned a deep blue, it may be interpreted to mean that there is enough HCl for the purposes of digestion.

3. *For Free HCl.*—Of many tests which have been suggested, I mention but one, the phloro-glucin-vanillin test. A solution consisting of two gms. phloro-glucin, one gm. vanillin, and thirty gms. absolute alcohol is prepared. A few drops of this are warmed in a white porcelain dish, with a cubic centimetre of the gastric fluid, when, if free HCl is present, a red color appears with the deposit of deep red crystals. This test is exceedingly delicate, and does not apply to any of the organic acids.

4. *Quantitative Test for HCl.*—The per cent. of this acid normally existing in the gastric juice has been variously stated, but may be assumed as about 0.2 per cent., with moderate limits of variation in either direction. Special importance attaches to its marked diminution or absence. At the period of full digestion HCl should be the only free acid in the stomach.

A roughly quantitative estimate of HCl may be made by diluting the gastric juice to a definitely measured amount, till it produces merely a yellowish sediment instead of one of a bright rose color. The weakest solution capable of producing a distinct tinge is 1 in 20,000. If, then, a given specimen has been diluted ten times to give this color, it originally contained .0005 of HCl.

For the accurate estimation of free HCl in the absence of other acids, a standard solution called the deci-normal solution of sodium hydrate is employed. Each cubic centimetre of this will neutralize .00364 gm. of absolute HCl. Into 10 c.c. of gastric fluid are dropped from a bottle enough of the alkaline solution to exactly neutralize it (the neutralization being determined either (*a*) by litmus paper, or better (*b*) by an alcoholic solution of phenolphthalleïn, which latter substance has the property of developing in alkaline solution a brilliant carmine color, which is absent in acid or neutral solutions). The point of exact neutralization being noted, the quantity of alkaline solution is observed ; *e.g.*, if 7 c.c. were required, there was in the 10 c.c. of stomach fluid .0255 gm. of HCl, or in 1 c.c., .00255, or about a quarter of one per cent.—rather a large quantity. Unfortunately this process is applicable only in the absence of the organic acids. If they are present their removal requires distillation of the stomach contents and the removal of the organic acids by ether.

5. *For Lactic Acid.*—The presence, however, of *lactic acid* may be demonstrated by mixing with a weak aqueous solution of chloride of iron a two per cent. carbolic acid solution. If gastric juice containing nitric acid be added to this a yellow color is produced. This test responds to a strength of lactic acid equal to $\frac{1}{4000}$, and is so delicate that the coincident presence of HCl does not usually interfere with it.

What is the significance of these conditions of acidity in the gastric juice ? Here we have to acknowledge considerable uncertainty. Absence of free HCl does not prove that none has been secreted ; for it is possible for it to have entered into combination with certain bases, and thus to have only seemed to be wanting. A few years ago it was claimed as a diagnostic point of great importance that cancer of the stomach was the cause, and

the only cause, of absence of HCl in the contents. But later observations go to show that this absence indicates a large extent rather than any special nature of structural lesion. While it is generally reduced in quantity, if not wanting, in cases of cancer, it may also disappear for months in gastric catarrh, and even in so-called nervous dyspepsia.

Riegel has claimed that in gastric ulcer the proportion of HCl is always abnormally high. Ewald has shown that it is generally in excess and always present. A conservative view would be that in a case clinically in doubt between ulcer and cancer, the presence of free HCl in large, or even in moderate amount, would be evidence of considerable weight in favor of ulcer.

Hyperacidity is a term applied to an increase in the proportion of HCl at the height of digestion; hypersecretion, to an increase in the amount of gastric juice, either continuous or occasional, and irrespective of the ingestion of food. The former may exist without the latter; but the latter generally presupposes the former. Hyperacidity, of course, contraindicates the exhibition of HCl, and calls for alkalies. Hypersecretion is to be suspected when, after thorough washing of the stomach, and some hours' fasting, a considerable quantity of gastric fluid can be expressed. This fluid is said to be generally acid, and capable of digesting albumin in the test-tube. Its presence is accompanied clinically by symptoms of pyrosis, eructations, and pain, and it occurs in some cases of so-called "nervous dyspepsia." It may be a cause of gastric dilatation. Lavage is the appropriate treatment both before and after the production of the ectasia.

The *duration of digestion* can be investigated only through the use of the stomach-tube. Seven hours should be enough to accomplish the complete digestion of any meal, and after that interval the stomach should be empty. The tube will show whether it is so. Undue quickness of digestion, while it can be detected through the same means, is of much less clinical significance.

Other evidence of value obtainable through the use of the stomach-tube relates to the size and position of the stomach. If the stomach be washed out, and so far as possible emptied, it can be inflated and its boundaries thus be made evident to percussion by attaching an ordinary rubber bulb syringe and injecting air till the organ is moderately distended. The advantage of this method over that of the separate introduction of powders which shall effervesce when conjoined is sufficiently obvious; the former method being less painful and being under the perfect control of the physician through the tube, which can be unstopped at any time. After the area of tympanites has been marked out, a small quantity of water can be introduced which will of course seek the lower border of the stomach and displace the air, thus substituting flatness for tympanites. Normally, but subject to considerable physiological variation, the cardiac orifice lies opposite the inner border of the seventh left rib; the pylorus a little below the margin of the liver, within a line connecting the right nipple with the umbilicus, the greater curvature reaching nearly to the umbilicus. But in cases of dilatation the greater curvature may extend to the sigmoid flexure. The significance of gastric dilatation is obstructed peristalsis. This is due to causes *a fronte*, chief of which is pyloric stenosis (usually malignant, less often from cicatrized ulcers), or else to causes *a tergo*, of which the commonest is lack of muscular tone.

The *kinesis*, or motor power of the stomach, is closely related in an inverse ratio to its dilatation. A test which has been used for measuring this power is the following: Salol is administered by the mouth. So long as it remains in acid gastric juice it is unaffected, but as soon as it passes out into the alkaline juices of the duodenum it forms salicylic acid, which is promptly eliminated by the kidneys. The test, applied to specimens of urine passed every fifteen minutes, is a drop of the tincture of chloride of iron added to the urine, which, when salicylic acid is present, strikes a deep red-brown color. Normally it is said that this occurs in thirty to forty-five minutes after the ingestion of the salol. But it is probable that this test, to show the actual motor power of the stomach, should be made to include the time necessary to secure the expulsion from the stomach of *all* the salol swallowed, and as the time needed for recovering this total amount of salicylic acid includes the time for emptying the stomach plus that of renal elimination, the test is left open to some doubt.

The *absorptive power* of the stomach may be very well shown by the iodine test. Five grains of iodide of potassium are administered in a gelatine capsule, which must be thoroughly wiped after it has been filled, so that none of the drug shall escape into the mouth. Beginning just before the capsule is swallowed, and at intervals of three or five minutes, the patient spits upon a piece of filter paper, which has been dipped into a solution of starch. These pieces of paper, numbered to distinguish them, are tested with a drop of fuming nitric acid. This sets free the iodine (if any exist) in the saliva, and a blue color is formed with the starch. When the absorptive power of the stomach is good, iodine should appear in the saliva in fifteen minutes.

Charles F. Withington.

DIGITALIS. Digitalis continues to maintain its position at the head of heart tonics. In England and America authorities are as one on this point. On the continent they are the same. Dujardin-Beaumetz assigns it the first rank and calls it "the type of heart tonics;" Professor Nothnagel places it above all other heart tonics, and Herr Fürbringer says, "the sovereign diuretic in cardiac disease has been, and still is, digitalis." Continued use has confirmed the confidence placed in it, and the innumerable rivals that appear serve only to bring its superior qualities into bolder relief. Not much has been added to the uses of this remedy, but we know more definitely its proper sphere, and apply it with more precision to the conditions in which it will prove of value.

In organic disease of the heart the guide for its use is the state of the compensatory action of that organ. It is not given as a remedy for the defective valves, nor with the expectation of benefiting any diseased condition of the organ; it is simply a stimulant and tonic to the muscular tissue. So long as the heart is able to overcome the impediment to the circulation and maintain a free flow of blood, nothing is to be gained by the use of the drug, but, with the earliest symptoms of failing power its administration must be commenced. The system responds quickly to the first indication of this loss of compensation, the heart beats more feebly and quicker, the pulse becomes irregular, a slight degree of dyspnœa is noticed, and œdema of the feet and ankles begins. In such conditions the beneficial action of digitalis is most marked. The heart beats more slowly and forcibly and propels the blood onward, the arteries become filled, the engorged veins relieved, and the equilibrium of the circulation is re-established. This slower action of the heart allows of a prolonged period of diastole, during which it is at rest and recuperating; the succeeding contraction is rapid and strong, due to the renewed strength and stimulating action of the remedy.

No form of organic disease contraindicates the use of digitalis when the compensatory action is failing. Its typical action is produced in mitral disease, in which it acts rapidly and for a prolonged period. In mitral stenosis it has been thought to produce a peculiarly important effect, as the prolonged dilatation of the ventricle permits a greater flow of blood from the auricle through the narrowed channel. In aortic disease it may also be given with confidence. The old idea that the prolonged diastole would allow the ventricle to become overfilled appears to be but little regarded now, as its beneficial effect outweighs any such danger. The following conclusions[1] indicate its purpose not only in aortic, but in all forms of valvular disease: (1) In all cases of valvular disease the chief desideratum in regard to the heart itself is the condition of the cardiac walls in respect to dilatation and hypertrophy; (2) that the presence, in cardiac disease of symptoms indicating a disturbance of the circulation always means failure of compensation; (3)

that the condition of over-hypertrophy or over-compensation does not exist; (4) that the dangers in aortic disease arise from the same cause as the dangers in mitral disease, that is, a failure of the ventricular muscle to perform the ever-increasing work put upon it; (5) that if digitalis is safe and beneficial in mitral disease it is equally so in aortic disease.

The one condition in which digitalis is contraindicated is fatty degeneration of the heart. In advanced stages of this disease, where the walls are thin and the cavities are much dilated, it must be used with extreme caution, as its action may be too violent for the feeble organ, and paralysis or rupture follow. In the lesser degrees of degeneration, where the evidences of such a condition are indistinct, a want of action on the part of the remedy is a sign that must not be disregarded. Dujardin-Beaumetz furnishes the following rule: "When in a patient, digitalis, administered methodically, managed with care, produces no amelioration on the part of the heart and pulse; when, above all, the quantity of urine is not augmented, be persuaded that there is a fatty degeneration of the heart and immediately cease the employment of the remedy."

A cumulative action, in the sense of an accumulation of the drug in the system followed by an outburst of increased action, is no longer feared. No such condition occurs. Toxic symptoms arise only from an overdose or from its prolonged administration, and the condition of poisoning is preceded by its regular train of symptoms. The first effect of digitalis[2] is to stimulate the vagus and the vaso-motor centres, which improves the action of the heart and increases the blood-pressure; this is followed by a relaxation of the vaso-motor apparatus, which is first evident in the renal vessels. Up to this point the drug produces its therapeutic action, the relaxed vessels in the kidneys, with a high arterial tension and powerful heart, furnishing all the conditions requisite for a free secretion of fluid. When the drug is pushed beyond this it produces the toxic symptoms: the renal vessels are relaxed, the reduced blood-pressure extends to the general circulation, the heart becomes weaker, and the circulation fails. When a fatal termination ensues it follows a continuance of this condition and ends with a failure of the heart, which is arrested in diastole. To avoid any ill effects it is safer to discontinue the drug for a few days, as soon as its action has been established; it may be administered again when required. Where the proper conditions for its use are observed there should be no danger of any toxic action; it is only when it is employed indiscriminately that any such effect arises. A case is reported[3] where no bad result followed its use for nearly three years, thirty-five drops being given three times a day.

The infusion appears to remain the popular preparation, particularly when its diuretic action is required. Among the French, a maceration in cold water is the favorite method of employing the drug, and is considered superior to the infusion. Five grains of powdered digitalis are macerated in four ounces of cold water for from eight to twelve hours, and then filtered. The dose is one tablespoonful every two hours. The tincture is preferred by some as a diuretic; it is probably the most useful preparation when a simple tonic action is required. Osler[4] considers that either preparation is efficient if the drug is of good quality and given in full doses—fifteen minims of the tincture or half an ounce of the infusion every three hours for two days, and then in reduced quantities. The subcutaneous employment of the infusion has been recommended. In this way it has been found that very small doses will act when larger doses have failed when given in the ordinary manner. The advantage over the administration by the stomach is that usually the gastro-intestinal mucous membrane is in a catarrhal and œdematous state and absorption is prevented. It is also thought that the action is retarded and altered by the passage through the liver. An infusion of three parts of the leaf in one hundred of water is prepared, and fifteen minims of this infusion have been injected twice or three times a day, it is said, with good results.

The relative value of the aqueous and alcoholic preparations assumes more importance when the solubility of the several constituents is considered. Of the four glucosides, digitoxin, digitalin, digitalein, and digitonin, the first three are freely soluble in alcohol; digitoxin is practically insoluble in water, digitalin only sparingly, and digitalein freely soluble in water. Digitonin is freely soluble in water, but hardly at all soluble in alcohol. Thus all alcoholic preparations contain the first three principles, and all aqueous solutions the last two. Therapeutically[5] the first three are very similar in action, producing the characteristic effects of digitalis; digitoxin being the most active. The fourth principle, digitonin, when isolated, has been found to be a direct poison to the muscular structure of the heart; it decreases its contractile power and produces a dilatation of the arteries. This toxic action is in a measure counteracted by the other principles when administered together. The whole question of the digitalins, however, remains very unsatisfactory; no true alkaloid has yet been separated; many varieties of digitalin are in the market, and the significance of the term varies according as it is given to a German or a French preparation.

Digitoxin—the digitalin of Nativelle—crystallized digitalin, the most active of all the principles, is the one generally employed to replace the preparation of the leaves, but it is uncertain and at times violent in its action and must be used with care. The dose is from $\frac{1}{1000}$ to $\frac{1}{600}$ grain, repeated two or three times a day. Huchard[6] uses a single large dose of $\frac{1}{200}$ grain daily, giving fifty drops of a 1 to 1,000 solution. Under this treatment he finds diuresis augmented, sometimes after a single dose, generally after a second or third. Foquet[7] recommends $\frac{1}{600}$ grain, to be followed by a daily dose of $\frac{1}{1000}$ grain. This has also been used hypodermically, but it proves painful and irritating.

Digitalis has been[8] recommended as a means of aborting pneumonia if given early and in large doses. The treatment has been followed by Professor Petresco, of Bucharest, in a large number of cases. He uses an infusion of one to three drachms of the leaves in eight ounces of water, and gives a tablespoonful every hour. As much as 120 grains of the leaves have been given in twenty-four hours. He states that these large doses abort the pulmonary process, shorten the attack, and hasten convalescence. The temperature in some instances drops from 105° to 96° F., and the pulse from 120 to 35 per minute. He thinks that this treatment would act almost as a specific if it could be commenced with the attack. In no instance were there any bad results, and the more severe the attack the better the action of the large doses. The good effects are due to the increased force of the circulation in the pulmonary tissue and the prevention of stasis and congestion. This can only follow the administration of large doses as early and as energetically administered as possible.

Professor R. Lepine[9] has employed digitalin in pneumonia also with success; $\frac{1}{200}$ grain was given in the morning and often $\frac{1}{100}$ or $\frac{1}{300}$ grain in the evening. He does not think that it has any specific action, but finds it of great value in supporting the action of a weak and feeble heart during the course of the disease.

DINAN. A watering-place and health-resort in the Department of Côtes-du-Nord, France.

Location.—Dinan is a picturesque old town, situated among some of the finest scenery in Brittany. It stands on a steep spur of land, overlooking the left bank of the river Rance. It is only about ten miles from Dinan to St.

Malo, and just as far to popular Dinard. The population of the place now exceeds 10,000.

ANALYSIS.—There is a cold chalybeate spring at Dinan, having the ordinary composition of a mild ferruginous water.

INDICATIONS.—Dinan is chiefly resorted to on account of its healthfulness and its proximity to the sea-coast. The waters are taken mainly by women and children with scrofula or chloro-anæmia.

ACCOMMODATION.—There are several moderately good hotels. The principal ones are the *Hôtel de la Poste, Hôtel de Bretagne, Hôtel de Commerce.* *Edmund C. Wendt.*

DINARD. A sea-side and climatic resort of growing fame and pretentions, in the Department of Ile and Vilaine, France.

Dinard is beautifully situated on the broad estuary of the river Rance, directly opposite to St. Malo. Little steamboats ply half-hourly between these resorts. It is favorably known on account of its agreeable climate, the fine beach, and the opportunity offered for many pretty excursions.

The old town of Dinard is nothing more than a fishing village, running along the sandy shore. The English are partly responsible for the existence of the new Dinard which overlooks the old village.

The accommodations are fairly good. The principal hotels are the *Hôtel de France, Franklin, Hôtel de Paris,* and the *Grand Hôtel de Dinard.* There is a small *Casino* and an *Établissement des Bains.* Although a typical French resort, English and Americans visit Dinard in increasing numbers. In recent years it has become more and more a resort for families, and both at Dinard itself and at the adjoining village of St. Enogat numerous furnished villas may be rented for the summer season, or for a shorter period. At the latter place the prices are somewhat more moderate than at Dinard. But in both these places, as in the great majority of French sea-side resorts, it is not quite safe to use the general water-supply for drinking purposes. The water should be boiled and then allowed to cool, or the bottled mineral waters should be used instead. During the past two or three summers a thoroughly competent English practitioner has been established at Dinard. *Edmund C. Wendt.*

DIPHTHERIA. INTRODUCTORY.—The first reference to this affection in New England, or, in fact, in America, is probably to be found in Sibley's "Harvard Graduates," vol. i., p. 94, where a number of children are said to have died from "bladders in the wind-pipe" in 1659. At various periods after this references to the disease are to be found, with some imperfect descriptions, as occurring in various parts of New England.

The modern history of diphtheria begins with the publication of Bretonneau's works, his first paper appearing in 1821. He asserted the identity of angina maligna (diphtheria) with membranous laryngitis (croup). He spoke of the continuity of the false membrane of the nose, pharynx, and respiratory tract, of its identity with some morbid processes of the skin, and asserted that diphtheria was a specific disease and not to be confounded with catarrhal or scarlatinal inflammation. He claimed also that it was a purely local disease, an opinion which he afterward modified. His completed monograph appeared in 1826.

From this time the literature of the disease becomes more and more voluminous year by year. Hardly a writer upon medicine or an investigator of the etiology of disease but has had more or less matter for publication. The points in dispute are, many of them, discussed to-day as vigorously as ever. The question of the identity of the two processes, croup and diphtheria, from a pathological stand-point, may be considered to be settled in the affirmative so far as to justify the assertion that true croup, or membranous laryngitis, may be one form of diphtheria.

The etiology of the disease, as to whether it is produced by bacteria, is no longer in doubt. This question has engaged the attention of many workers, and the solution seems to be reached at present.

Since Bretonneau the principal contributions to the history of the disease have been made by Trousseau, Bourdeoise, Baumgarten, Rilliet and Barthez, and Virchow. In 1847, the latter first made the distinction between the catarrhal, croupous, and necrobiotic varieties of laryngeal affections.

SYMPTOMATOLOGY.

SYMPTOMS IN GENERAL.—The symptoms may vary from those of the slightest sore throat to those of the most serious and malignant disease. For convenience these may be separated into several forms, according to the severity of the symptoms.

1. The typical form.
2. The catarrhal, or mild form.
3. The malignant form.
4. (Which is rare) the chronic form.

1. *The Typical Form.*—A typical case of diphtheria presents about the following phenomena: After a general feeling of malaise, or loss of tone, lasting from two to five days, the attack commences with a definite constitutional disturbance. The first stage presents a rapid rise of temperature, often reaching 103° or even 105° F., a feeling of chilliness, anorexia, nausea, and occasionally vomiting and diarrhœa. The throat early becomes dry and hot, with pain upon swallowing, and the neck is swollen, stiff, and tender. The tonsils, pillars of the fauces, uvula, and back of the pharynx, are red, swollen, turgid. The appearance of the false membrane does not occur until the arrival of the second stage. In this a viscid, yellowish secretion will be seen, gradually forming in the depressions of one or both tonsils. Later, certain points of the superficial mucous membrane become infiltrated with a yellowish material, these points being somewhat elevated above the general surface. These points, at first more or less translucent, become opaque and grayish-white. They extend and coalesce and thus a considerable surface of the fauces and pharynx may become covered with a pseudo-membrane, which is constantly being reinforced by additions to its under surface. Portions of the membrane may be drawn off, and occasionally a perfect cast of the place from which it is removed may be obtained. The neck is swollen from the enlargement of the parotid and submaxillary glands, which are frequently hard and very tender. Fever is generally lessened with the appearance of the exudation; exceptionally, however, it may remain as high as, or even rise higher than, it was at first. Swallowing is performed with difficulty, and the breath is fetid from the decomposition of the morbid secretion. The pulse is weak and compressible, and is either very rapid or very slow. The first sound of the heart is weakened, albuminuria is a frequent symptom in the earlier stages of an attack, and the urine is apt to become scanty and high-colored. Hyaline casts are not uncommon, but the occurrence of granular or epithelial casts is not constant. The morbid process may spread downward and invade the larynx and trachea, this usually occurring in from three to four days after the invasion, and making itself manifest by unmistakable signs. These are: hoarse, muffled voice, stridulous breathing, constant dry cough at first, later dyspnœa, increasing cyanosis, swelling of the face, and drowsiness passing into coma. The nasal cavities may be involved primarily, or by the extension of the disease from the fauces. This is indicated by the discharge from the nose of a fetid, dark-colored watery fluid, with the formation of false membrane in the nasal cavity. There is often, also, repeated, and sometimes fatal, nasal hemorrhage, and occasionally there occurs a blocking of the lachrymal ducts, or the disease may extend by this channel to the eye.

Trousseau goes so far as to say that he has never seen a case of diphtheria recover in which hemorrhage from the nose occurred. The morbid process may also pass through the Eustachian tube to the tympanic cavity, and eventually cause a perforation of the membrana tympani, with subsequent purulent discharge from the ear. If the

larynx be not attacked, the third stage is reached and the disease slowly disappears or death occurs very rapidly. If the result is to be favorable, a marked improvement takes place in all the symptoms by the end of the first or the beginning of the second week. The temperature becomes normal, the pulse regains its strength and regularity, and anorexia disappears, the congestion of the fauces diminishes, the exudation ceases to extend, and portions of it become detached. The patient feels very well, but the danger is not passed, for a relapse may occur which may be more severe than the initial attack.

Another danger to be feared at this time is syncope from failure of the action of the heart. If the termination of the attack is unfavorable, death may occur from a secondary blood-poisoning with typhoid symptoms or coma, or, more frequently, from cardiac embolism or syncope.

2. *The Mild Form.*—In a case of this character the symptoms are often so slight that the diagnosis must be excessively doubtful, the symptoms being those of an ordinary catarrhal sore throat. The constitutional disturbance is very slight; the elevation in temperature being but one or two degrees, and the pulse being but little affected.

There may be slight pains or dryness in the throat, and some difficulty in swallowing. The submaxillary glands may be swollen and tender; the tonsils, soft palate, and pharynx red and swollen; and in a day or two minute yellowish spots, the size of a pin-head, may make their appearance. These are easily removable.

The symptoms improve on the third or fourth day, and often the presence of persistent and general weakness is the only definite sign that the case has been one of diphtheria. This form is often, however, introductory to an acute attack, which breaks out in a few days in full force, and the definite diagnosis can only be made by means of the bacteriological examination.

3. *The Malignant Form.*—In a case of this kind there are at once rigors, headache, vomiting, and, not infrequently, epistaxis. The throat symptoms are not always very severe, but decomposition of the secretion and the resulting fetor are very marked. The temperature is not necessarily high; the pulse is small, rapid, and wavy. The patient becomes drowsy; the skin is cold and clammy; the face pale, the tongue dry, brown and tremulous; the mucous surfaces bleed easily, and petechiæ under the skin are often present. All the symptoms of a typical case develop rapidly one after the other, and the patient dies comatose or in syncope.

4. *Chronic Diphtheria* is rare. Mackenzie ("Diphtheria," p. 31) quotes a case in which the membrane persisted in reforming for a period of three months. Other cases have also been reported in which this repeated formation of membrane was a characteristic feature.

Symptoms in Detail.—*Prodromes.*—In a majority of cases there is a prodromic stage lasting for a day or two. The patient feels indisposed to exertion; is slightly feverish, and is apt to have some difficulty in deglutition. There may be headache with occasional vomiting.

Pharynx and Soft Palate.—The pharynx and soft palate are the principal seats of the local diphtheritic disturbance; larger or smaller deposits being found there, loosely attached or deeply embedded according to the location. Sometimes there is but one spot, but usually there are several, and in a short time (twelve to twenty-four hours) they coalesce to form a membrane. On the uvula, soft palate, and posterior wall of the pharynx the membrane is superficial and may sometimes be easily removed. It is more firmly attached upon the tonsils, and sometimes extends into the deeper tissues. There is, occasionally, no actual membranous formation, and in such cases the tissues are swollen, the mucous membrane is more or less reddened, and the infiltration into the tissues gives a somewhat grayish-white discoloration. When the uvula is involved the swelling is usually more conspicuous than when the rest of the fauces alone is affected.

Jacobi speaks of three distinct processes in the throat: 1, A membrane lying on the mucous membrane, and which can be separated without much, if any, injury to the subjacent epithelium; 2, a membrane implicating the upper layer of the mucous membrane; 3, a whitish or grayish infiltration of the surface and deeper tissues which may occasion necrotic changes. When the symptoms are of long duration, and deep infiltration occurs, hemorrhages from the affected parts are not uncommon. They may be slight, but occasionally large vessels are opened and death may result. Gangrene sometimes occurs after extensive infiltration has taken place, and a decided loss of substance is revealed after the falling off of the membrane, which loss of substance more usually takes place upon the tonsils.

The Nasal Cavities.—The morbid process often passes into the nasal cavities from the posterior aspect of the soft palate or pharynx, especially when the uvula is affected. The disease may also occur primarily in the nose, and this happens more often after an acute catarrh. The secretion is very profuse, slightly flocculent, and frequently very offensive. The first certain indication of nasal diphtheria is the occurrence of tumefaction of the cervical glands. Before this it is often impossible to diagnosticate the disease in this situation. This adenitis is often found very persistent, a permanent induration sometimes remaining. Chronic nasal catarrh, with elongated uvula and enlarged tonsils, are frequent results of the disease.

The Eye.—The eye is frequently affected by extension of the process from the nose through the nasal duct, although it may also be a seat of primary infection. Diphtheritic conjunctivitis is an exceedingly grave affection, as regards the safety of the eye; the cornea often being destroyed by pressure, from diphtheritic keratitis, in twenty-four hours. Von Graefe first studied diphtheria of the eye in 1854. It is not a frequent affection. Sometimes a single eyelid is the seat of the disease. The process may first appear on the conjunctiva bulbi, and pass from this to the conjunctiva palpebrarum. The cornea becomes hazy very early, and ulceration occurs, as a result of which perforation is to be feared, with possible prolapse of the iris and consequent destruction of the eye, or, at least, loss of sight.

The Ear.—The ear may become affected by way of the Eustachian tube, and an acute otitis media may develop, with perforation of the membrana tympani, and even necrosis of the mastoid bone. An otitis interna is also sometimes observed.

The Epiglottis.—It is not rare to find patches of membrane in the depression at either side of the face of the epiglottis, which is then swollen, with hard and reddened edges; the great part of the diphtheritic process occurring upon its upper surface. Dyspnœa and hoarseness are only occasional, and only when there is accompanying œdema at the entrance to the larynx. This œdema produces a functional paralysis of the vocal cord, with marked dyspnœa upon inspiration.

Larynx.—When membrane forms in the larynx inspiration and expiration are both interfered with. Fever and pain are not necessarily prominent, but, as the process goes on, the respiration becomes more difficult, complete aphonia comes on, and the hoarse, croupy cough becomes more and more suppressed. If the affection progresses, all the symptoms of suffocation and poisoning by carbonic acid gas may be observed. The supra-clavicular and intercostal regions are retracted with each inspiration, sometimes also the ensiform cartilage. Usually a number of days elapse between the first laryngeal symptoms and death. At times, however, a fatal result occurs in a few hours.

Trachea.—Jacobi and a few others claim that the trachea and bronchi may be the original seat of the disease, and that the diphtheritic process may spread upward to the larynx and into the fauces. This is denied, however, by Henoch, Oertel, and Steiner. Cases of genuine adhesions between the arytenoid cartilages, with a resulting paralysis of the internal thyro-arytenoid muscles, have been occasionally reported.

The Lungs.—Lobular pneumonia is the occasional result of the inhalation of pieces of false membrane into the

smallest bronchi. Fibrinous pneumonia is also known to occur. Broncho-pneumonia frequently develops after the trachea becomes affected. In all these forms the diagnosis is extremely difficult if the larynx be affected, because of the noisy respiration which interferes with the recognition of the signs upon auscultation. If the trachea is open, this difficulty is done away with.

The Mouth.—Primary infection of the mouth is not common. Diphtheria often occurs in this situation, however, in association with the same affection in the nose and the fauces. The morbid changes occur on the cheek, tongue, angles of the mouth, gums, and lips, appearing here as in other places by preference where there has been a solution of continuity in the mucous membrane. Diphtheria of the mouth is an indication of a probable long duration of the disease, with the danger of septic poisoning following.

Œsophagus and Cardiac Orifice of the Stomach.—The occurrence of genuine diphtheria of these parts is asserted by some authorities, while others say that the formation of membrane ceases at the upper portion of the œsophagus. Intestinal diphtheria occurs, but is rare in the human subject, although not uncommon in cows and certain other of the lower animals. Wounds of all kinds are easily and rapidly infected and may quickly become covered with the false membrane. Death occurs by general infection from such a source, and may come as well from diphtheritic infection of abrasions of the skin as from that of wounds resulting from amputation or other surgical interference.

The Skin.—At the beginning of an attack, sometimes not for two or three days, a more or less general erythema may appear upon the skin. Its principal seat is over the shoulders, chest, or back, and it is very similar to, and often indistinguishable from, the eruption of scarlatina. Erysipelas also often occurs, and is a complication much to be dreaded.

Genito-Urinary Organs.—The diphtheritic process may occur in these organs secondarily, but not often. Sometimes it is primary in this locality. The disease has occurred in the vulva, the vagina, and the bladder, and in circumcision wounds.

The Kidneys.—These are the most actively involved of any of the internal organs during the progress of diphtheria. Wade, in 1858, first spoke of albuminuria in this disease, and was followed some months later by Sée (in the *Union Médicale* for 1858, p. 407). The presence of albumin is not of such great significance as was at first supposed. It occurs in large quantities in mild cases, and in small amounts or not at all in severe attacks. It may appear either before or after tracheotomy. It is often unaccompanied by any other sign of renal disease, but may be accompanied by various kinds of casts and epithelial cells.

The Heart and Blood.—There may be weakness of the cardiac muscles, sluggish circulation, dyspnœa, and muffled heart-sounds, cool and pale skin, feeble and frequent, sometimes slow, pulse. Occasionally there is actual endocarditis affecting the valves, more especially the mitral. This is characterized by high fever, precordial pain, syncope, and a systolic murmur.

The Nervous System.—This is often affected, and frequently very seriously. The influence exerted was supposed for a long time to be localized in certain nerves, or groups of nerves, and that the first points attacked were always the arches of the soft palate. This is not true, however, nor is the assertion that severe paralyses follow severe local manifestations, for the opposite is very often the case, viz., that a very mild attack of diphtheria may be followed by a very severe form of paralysis. Many theories of the method of production of this paresis are put forward, such as, that they are produced by fatty or granular degeneration of the muscular fibres, or by capillary hemorrhages, or by amyloid degeneration, or by œdematous infiltration of the part and consequent pressure. All of these, however, are more speculative than based upon actual facts observed.

The most frequent paralysis is that of the soft palate, which appears, as a rule in the second week, although often earlier and sometimes later. Paralysis of the constrictor muscles of the pharynx also may occur, and these two conditions produce imperfect speech and difficult deglutition, with frequent regurgitation of fluid through the nose. In such cases sometimes life can only be sustained by the use of the œsophageal tube. Paralysis of the power of accommodation comes next in frequency. Then follow paralyses of the lower and upper extremities, these rarely occurring suddenly, and usually involving only one set of muscles at the same time. Complete fatty degeneration, although rare, may occur. The muscles of the neck are sometimes affected, producing inability to hold the head erect. The fingers alone may be paralyzed. The bladder and sphincters may be affected, but this is not a common occurrence. Sometimes the muscles of respiration are attacked, such cases being very apt to terminate fatally. We have thus far spoken only of motor paralysis, but affections of the sensory apparatus may also occur. Anæsthesia of the entire upper part of the body has been observed. Sometimes the two are combined and locomotor ataxia is the result. Diphtheritic paralyses are irregular in regard to the place of appearance, their severity, their duration, and their responsiveness to treatment. They may last from six weeks to six months, may recover with treatment and without it, and may prove refractory to anything that can be done to remove them.

Pathological Anatomy.

The most important part of the diphtheritic process is the false membrane. It is the most prominent characteristic, as well as the one most frequently met with. It is tough, dry, yellowish, or grayish-white, firm and elastic. It swells upon the addition of acetic acid and becomes more or less transparent. It is soluble in caustic alkali, insoluble in water, and yields neither gelatine nor albumin. It varies in appearance from a thin transparent pellicle to a skin of considerable thickness. On separation, if the attack has been a mild one, the subjacent mucous membrane is found to be smooth and paler than normal; if the attack has been severe, more or less ulceration is left behind. The membrane consists, first, in great part of fibrin, the result of epithelial changes, or a direct product from the exuded blood-serum. It contains, also, epithelium, more or less degenerated blood, mucus, and bacteria.

Its method of formation is somewhat as follows: The pavement epithelium becomes cloudy, swollen, and dentated, and dissolves into a net-work. It becomes, later, the recipient of newly formed cells. There is a considerable infiltration of the mucous membrane with pus cells and granules. The cellular tissue is studded with granules also, its decomposition resulting in a fine granular deposit and necrosis—a process considered by Virchow to be an important element in severe forms of diphtheria.

The clinical differences between the membrane of croup and that of diphtheria are not borne out by the microscopical examination, which shows no essential discoverable difference.

The Heart.—This organ is often found to be perfectly healthy. It may present numerous petechiæ and there is often fatty degeneration of the muscular tissue, and parenchymatous inflammation or hemorrhages may occur. Endocarditis is found affecting the mitral more often than the tricuspid or pulmonary valves. Perforation of the septum of the right auricle and of the aorta has been seen.

Lungs.—These organs present various inflammatory or congested appearances; œdema, broncho-pneumonia, atelectasis, emphysema, ecchymoses, and infarction are all found at various times. The lungs may also be entirely unaffected.

The *spleen* is often increased in size and congested, and it may be friable, with more or less extensive infarctions.

The *kidneys* may be normal, simply congested, or the seat of parenchymatous or interstitial nephritis.

In the *muscles* are sometimes found ecchymoses, myositis, gray degeneration, or atrophy.

The *lymphatic glands* are also swollen and inflamed. They may be hard or yielding to pressure. Abscesses are not common. The tissue about the glands is often involved in the inflammatory process also.

Intestinal Canal.—Unless the actual seat of the disease this tract presents no peculiar appearance. Virchow considers that diphtheria of the intestinal canal is characterized by fibrinous deposits on the surface and in the tissues of the intestine, with a subsequent granular degeneration of the tissues, and Radjewsky claims that his experiments prove that bacteria are important factors in the production of the diphtheritic membrane after previous inflammation has taken place in the intestine.

The Brain.—If death has occurred from asphyxia, the brain presents a venous engorgement of the membranes and cerebral structure, with minute extravasations of blood. Pus and lymph have also been found on the arytenoid in cases in which mental disturbances have been very marked. In many cases, however, there are no perceptible alterations in the cranial cavity.

Etiology.

Diphtheria is pre-eminently a disease of early life, the proportionate number of cases diminishing very rapidly as the age increases. Of five hundred deaths in Vienna from this disease in 1868, but one case had reached the age of sixty. Sex seems to exert no special influence. It occurs mostly in children; the predisposition of this age is explained by the softer condition of the mucous membrane of the mouth and pharynx, and by the narrowness of the pharynx, the protuberant condition of the tonsils, the large number and size of the lymphatics, and the greater communicability between them and the system at large, all of which aids in the development of the disease. On the other hand, the free acid secretions of the mouth after the third month tend to hinder its occurrence after this period. There seem to be families in which there is an apparent predisposition to this disease.

Climatic and Atmospheric Conditions.—The disease is most common in temperate climates, but it occurs almost everywhere. It is probable that moisture favors the development of the poison, and also that it can lie dormant for a long time, and until some special agency calls it into activity.

The disease prevails more extensively during the winter months, apparently at the time when catarrhal conditions are most common, and the mucous membrane is in a receptive condition. Social position offers no safeguard during an epidemic, although sporadic cases seem to especially attack those living under bad hygienic surroundings. Exhalations from sewers and filthy personal habits are also said to produce the disease, but the weight of evidence is against their possessing anything more than a favoring action.

Manner of Infection.—Whether diphtheria be a local disease with constitutional sequelæ, or whether it be a general disease making its most marked appearance at certain points, is a question which has been much discussed. If, however, as is practically certain, it is excited by the activity of a micro-organism, the question is settled that the local manifestations are usually the signs of the place of entrance, and the constitutional disturbances the evidence of the general distribution of the poison.

The infectiousness of diphtheria is undoubted. The infectious material may be communicated directly by the patient, and it seems to cling to solid bodies, and may be transported in this way to a distance, but how far is, as yet, undetermined.

The methods of transportation which have been thought to offer the most usual channel for the spread of the disease are milk of diseased cows and infected animals. Many researches make it certain that the disease occurs among domesticated animals, although the more recent investigations seem to indicate that it is really a disease resembling human diphtheria as regards its clinical symptoms, but differing from it in the fact that it is produced by a micro-organism which differs somewhat from the true diphtheria bacillus. The question being determined in the affirmative may furnish a probable explanation of the origin of many cases in human beings in which the source of infection has been obscure.

The Nature of the Diphtheritic Poison.—Investigation of this point has occupied the attention of observers for years past. As long ago as in 1840 Henle expressed his belief in a contagium vivum, and Buhl first found micro-organisms in the diphtheritic membrane, but he expressed no opinion as to their special import.

The work of Loeffler, first published in 1884, described a specific micro-organism which he had found in the tissues of individuals suffering from diphtheria. This discovery has been confirmed by so many observations and by so many different observers since that time, that the question of the specific infectious agent in diphtheria must be considered as definitely settled at the present time. This question is one of such great importance, and the disease is one in which positive therapeutic results seem to be so clearly promised, that it has been thought best to give a full description of the organisms found in the diphtheria of men and of the lower animals.

The Bacteria Occurring in Diphtheria.—For the following summary of the present state of opinion in regard to the bacteria of diphtheria, we are very largely indebted to the admirable *résumé* of the work done, and the views entertained, by various authors, to be found in Sternberg's "Manual of Bacteriology" (published by William Wood & Co., New York, 1892).

The condition of the question in regard to a specific organism occurring in diphtheria is such that to-day we have a very precise knowledge of the specific infecting agent, together with evidence that it produces during its growth a very potent toxic substance, the absorption of which from the seat of local infection accounts, in a satisfactory manner, for the general symptoms of the disease, which are due to a toxæmia and not to an invasion of the blood and tissues by the pathogenic micro-organisms producing it, although the latter statement seems likely to be more or less modified by future investigation, as is indicated by the work of Frosch, quoted in this article. Many examinations have failed to demonstrate the presence of bacteria in the blood of patients suffering from diphtheria, but a variety of micro-organisms have been obtained in cultures from diphtheritic pseudo-membranes, and among them are the well-known pus organisms, especially the streptococcus pyogenes, that is apparently very commonly present and is perhaps the active agent in the production of certain forms of pseudo-diphtheria. But the malignant specific diphtheria has been shown to be due to a bacillus first recognized by Klebs in 1883, and cultivated and described by Loeffler in 1884. In his first article, the latter author did not claim to have fully demonstrated the etiological relationship of this organism, but his own later work and that of many others show constant success in finding the same bacilius in other cases of diphtheria, and the same successful result from inoculation experiments with pure cultures of the organism in certain of the lower animals.

There has also been found, by Loeffler and others, an organism that does not possess pathogenic properties, but which resembles very closely the diphtheritic bacillus. And to this organism has been given the name of the *pseudo-diphtheritic bacillus*. It is still uncertain whether this bacillus is to be considered a distinct species or a non-pathogenic variety of the true diphtheria bacillus, as is maintained by the French authors Roux and Yersin.

The evidence upon which the bacillus of diphtheria is now generally conceded to be the specific infectious agent in true diphtheria rests upon the following principal points:

1. It is found in all undoubted cases of diphtheria, and in support of this there are the results of experiments and researches made by a very large number of experimentalists who, in nearly every case, have demonstrated without difficulty the presence of this bacillus. The one

eminent observer who failed to find the organism, in a series of twenty-four cases studied by him, was Prudden, of New York. But later, in a subsequent series of twelve cases, Prudden obtained Loeffler's bacillus in cultures from eleven, and he says, "We are now, it would seem, justified (as it did not appear to the writer that we were two years ago), owing to the large number of important researches which have been made in the interim, to maintain that the name diphtheria, or, at least, primary diphtheria, should be applied, and explicitly applied, to that acute infectious disease usually associated with a pseudo-membranous inflammation of the mucous membrane, which is primarily caused by the bacillus called bacillus diphtheriæ of Loeffler."

In this country Welsh and Abbott have also demonstrated the presence of the Loeffler bacillus in a series of cases occurring in Baltimore, and have proved its specific pathogenic power by inoculation in animals.

Loeffler attempted to show how long after convalescence the diphtheria bacillus may be present in the throat of an infected person, and, in a typical case, a bacteriological examination was made daily, from the commencement until fourteen days after its termination. The fever disappeared on the fifth day and the exudation had all disappeared on the sixteenth day. Up to this time the bacillus was daily obtained in cultures, and subsequently nearly every day up to the twenty-fifth, that is, for three weeks after the febrile symptoms had disappeared.

Roux and Yersin have also obtained the bacillus in cultures from mucus scraped from the throat of convalescents several days after the disappearance of all evidence of the disease.

2. The Klebs-Loeffler bacillus is found only in diphtheria. In his earlier researches Loeffler obtained the bacillus in a single instance from the mouth of a healthy child, and this fact led him to hesitate in announcing it as his conviction that it was the true cause of diphtheria.

But in extended researches made subsequently, he has not again succeeded in finding it except in association with diphtheria, and he admits now that he may have been mistaken as to the identity of the bacillus found. This seems not improbable, in view of the fact that very similar bacilli have been found by various bacteriologists. Von Hoffman obtained a similar, but non-pathogenic bacillus from the mucus of chronic nasal catarrh, and from a healthy mucous membrane; Babes, from cases of trachoma; Neisser, from ulcers; Zarinko, from the surface of various mucous membranes; but all of these were shown to possess certain differences in their biological character by which they could be differentiated from the true diphtheria bacillus.

Welsh and Abbott in their comparative studies did not find the Loeffler bacillus, "or any bacillus that an experienced bacteriologist would be likely to confound with it." They examined mucus from the throat of healthy children; from those suffering from simple inflammation of the tonsils and pharynx; and from four cases of so-called follicular tonsillitis. As a result of their investigations they agree with Loeffler and with Roux and Yersin as to the great practical value, for diagnostic purposes, of a bacteriological examination, by cover-glass specimens and by cultures, of cases in which there is any doubt of the true character of the disease. They say further, "the only species of bacteria which we have found constantly in the cases of diphtheria have been the Loeffler bacillus. Two other species have been present in many cases, namely, the well-known streptococcus, which grows in much smaller colonies and less rapidly than the Loeffler bacillus, and a short, oval, often slightly pointed bacillus, growing in long chains running parallel to each other. There are often marked irregularities in shape, and especially in size, of this bacillus, even in individuals of the same chain. The colonies of this bacillus are grayish-white, moist, larger than those of the streptococcus but smaller than those of the Loeffler bacillus."

3. As shown by Loeffler's earlier researches, pure cultures of this bacillus induce characteristic diphtheritic inflammation when inoculated into the mucous membrane of certain of the lower animals. Roux and Yersin have also shown that local paralysis is as likely to occur in inoculated animals as it is in a case of diphtheria in man.

In speaking of their inoculations into the trachea in rabbits these investigators say the affection which is thus induced in the rabbit resembles croup in man. The difficulty which the animal experiences in breathing; the noise made by the air in passing through the obstructed trachea; the aspect of the trachea, which is congested and covered with false membrane, and the œdematous swelling of the tissues and glands of the neck make the resemblance absolutely remarkable.

Welsh and Abbott give the following account of the results of inoculation into the trachea in kittens. A half-grown kitten is inoculated in the trachea with one platinum loop from a pure culture of the Loeffler bacillus on glycerine-agar eleven days old. For this inoculation a small median incision was made over the trachea, and in the latter a hole just large enough to admit the platinum loop was made. The culture was rubbed over the mucosa of the trachea for an extent of about three centimetres in length, and in this process sufficient force was used to abrade the mucous membrane. On the day following the inoculation no special alteration in the animal was observed, but on the morning of the second day it was found to be in a very weak condition. In the course of this day it became so very weak as to lie completely motionless, apparently unconscious, with very feeble, shallow respiration. Several times it was thought to be dead, but on careful examination it was found still to be breathing feebly. It was discovered dead on the morning of the third day. At the autopsy the wound was found gaping and covered with a grayish, adherent, necrotic, distinctly diphtheritic layer. For a considerable distance around the wound the subcutaneous tissues were very œdematous, the œdema extending from the lower jaw down over the sternum and to the side of the neck, and along the anterior extremities. The lymphatic glands at the end of the jaw were markedly swollen and red. The mucous membrane of the trachea, beginning at the larynx and extending down for six centimetres, was covered with a tolerably firm, grayish-white, loosely attached pseudo-membrane, in all respects identical with the croupous membrane observed in the same situation in cases of human diphtheria.

The account which we have just given, together with many others that might be quoted, seems to show that the organism spoken of and studied by so many observers, is unquestionably the cause of the specific disease, diphtheria. As has already been inferred, it is also unquestionably true that there may be other processes *clinically resembling diphtheria* which involve the throat and other mucous surfaces, and which owe their origin to other bacteria.

Description of the Bacillus of Diphtheria.—It was first observed in 1883 by Klebs in diphtheritic false membrane. It was first isolated in pure culture and its pathogenic power demonstrated by Loeffler in 1884. It was found in diphtheritic pseudo-membranes, and especially in the deeper portions, intermingled with numerous other bacteria, while the superficial layers of the membrane commonly contained a few cells or bacilli, or were invaded by other species, especially by the streptococcus pyogenes. The bacilli may not be found in the affected mucous membrane, or in sections from the internal organs in fatal cases of this disease, although recent bacteriological examinations by various authors have shown their pretty constant occurrence in these situations (see Frosch, *infra*).

Morphology.—The organism is a rod, straight or slightly curved, with rounded ends, having a diameter of from one-half to eight-tenths of a micromillimetre, and from two to three micromillimetres in length. Irregular forms are very common, and, indeed, are characteristic of this bacillus. In the same culture, and especially in an unfavorable culture-medium, very great differences in form and dimensions may be observed, one or both ends appearing swollen or the central portion be-

ing notably thicker than the extremities, or the rod may be made up of irregular, spherical, or oval cells. Multiplication occurs by transverse subdivision only, and the bacilli do not appear in long chains at any time. In unstained preparations certain portions of the rod, and especially the extremities, are observed to be more highly refractive than the remaining portion, and in stained

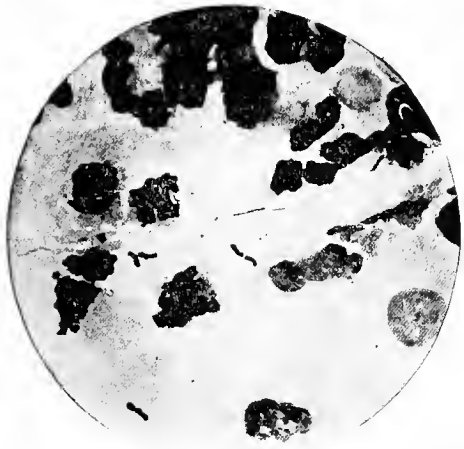

FIG. 152.—Diphtheria Bacillus, from a Diphtheritic Membrane in the Trachea. Cover-glass preparation, stained with alkaline methylene blue. (× 1,000.) (Fraenkel.)

preparations these portions are seen to be more deeply colored. The bacillus may be stained by the use of Loeffler's alkaline solution of methylene blue, but is not so readily stained with some of the other aniline colors commonly employed. It is stained also by Gramm's method.

For the demonstration of the bacillus in sections of diphtheritic membrane, nothing can surpass in brilliancy and sharp differentiation, sections stained doubly by the modified Weigert fibrin stain and picro-carmine (according to Welsh and Abbott).

Biological Character.—The diphtheria bacillus is aëro-

bic, non-motile, and non-liquefying. It does not form spores. It grows most freely in the presence of oxygen, but is also a facultative anaërobic organism. Development occurs in various culture-media at a temperature of from 20° to 42° C., the most favorable temperature being about 35° C. It grows very readily in nutrient gelatine, having a slightly alkaline reaction, in nutrient agar, in glycerine agar, or in alkaline bouillon. But the most favorable medium appears to be that first recommended by Loeffler, which consists of a mixture of three parts of blood-serum with one part of bouillon, the latter containing one per cent. of peptone, one per cent. of grape-sugar, and one-half of one per cent. of sodium chloride.

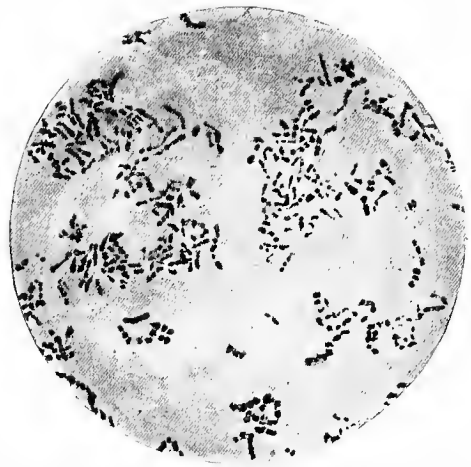

FIG. 154.—Diphtheria Bacillus. Culture on solidified blood-serum. Cover-glass preparation, stained with alkaline methylene blue. (× 1,000.) (Fraenkel.)

This mixture is sterilized and solidified at the temperatures usual with blood-serum, and upon it the development is so rapid in the incubating oven that at the end of twenty-four hours the large, round, elevated colonies of a grayish-white color and moist appearance may be easily recognized, while other associated bacteria have, as a rule, not yet developed colonies large enough to interfere with the recognition of those of the diphtheria bacillus. Upon nutrient agar plates the deep-lying colonies, when magnified about eighty diameters, appear as round or oval, coarsely granular disks, with rather ill-defined margins, or, when several colonies are in juxta-

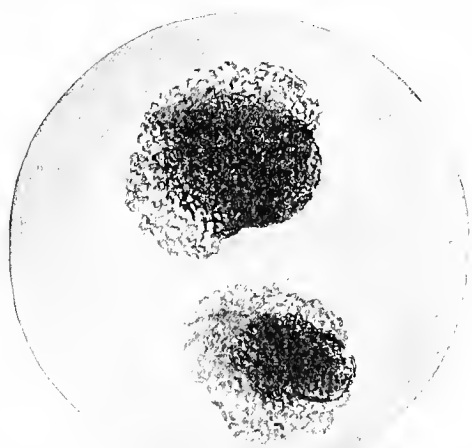

FIG. 155.—Diphtheria Bacillus. Colony on agar plate, twenty-four hours old. Unstained. (× 100.) (Fraenkel.)

position, as figures of irregular form. The superficial colonies are grayish-yellow in color, have an irregular, not well-defined outline, and a rough, almost reticulated surface. The growth upon glycerine agar is very similar.

The first inoculation in a plain nutrient agar tube often gives a comparatively feeble growth, which becomes

more abundant in subsequent inoculations in the same medium. In needle cultures in glycerine, or plain agar, growth occurs to the bottom of the line of inoculation, and also upon the surface, but is not at all characteristic. The same may be said in reference to cultures in nutrient gelatine. Plate cultures in this medium containing fifteen per cent. of gelatine at 24° C., give rather small colonies, which are white by reflected light, and under the microscope are seen as yellowish-brown opaque disks, having a more or less irregular outline and a granular structure. In alkaline bouillon the growth is sometimes in the form of small whitish masses along the side and bottom of the tubes, but at other times a diffusely clouded growth occurs in this medium. After standing for some time in the incubating oven, a thin white pellicle may form upon the surface of the bouillon. The reaction of the bouillon becomes at first acid, but later it is alkaline.

With reference to the growth on potato, authors have differed, probably because the growth is slightly visible. Welsh and Abbott say: "Our experience has been that the bacillus of diphtheria grows on ordinary sterilized potato without any preliminary treatment, but that the growth is usually entirely invisible, or is indicated by a dry thin glaze after several days. Doubtless the invisible character of the growth has led most observers into the error of supposing that no growth existed, whereas a microscopical examination reveals a tolerably abundant growth, which on the first potato is often feebler than on succeeding ones. Irregular forms are particularly numerous in potato cultures, and in general the rods are thicker than on other media. In twenty-four hours, at a temperature of 35° C., microscopical examination showed distinct growth. We have cultivated the bacillus for many generations on potato."

Milk is a favorable medium for the growth of this bacillus, and as it grows at a comparatively low temperature in it—20° C.—it is evident that this fluid may become a medium for conveying the bacillus from an infected source to the throat of a previously healthy person.

Cultures of the diphtheria bacillus may retain their vitality for several months, and when dried upon silk thread for several weeks, colonies may still develop in a suitable medium. Its drying has been found not to destroy its vitality for a period as long as from three to four weeks, when the desiccation process took place in a room, or for a period of from five to ten weeks (in one instance fourteen weeks), when the desiccation took place in an exsiccator. In dried diphtheritic membranes, preserved in small fragments, the bacillus retained its vitality for a period of nine weeks, and in larger fragments for one of from twelve to fourteen weeks. The thermal death-point, as determined by Welsh and Abbott, is 58° C., the time of exposure being ten minutes. Loeffler had previously found that it did not survive exposure for half an hour to a temperature of 60° C.

Pathogenesis.—In view of the evidence that has heretofore been recorded, it may be considered as demonstrated that this bacillus gives rise to the morbid phenomena which characterize the fatal disease in man known as diphtheria.

The effects of inoculation in rabbits and cats have already been referred to, these giving rise to a characteristic diphtheritic inflammation with general toxæmia and death from the absorption of soluble toxic products formed at the seat of local infection.

This inference as to the cause of death seems justified by what we know in regard to the life history of the bacillus, and is supported by additional experimental evidence given below.

Subcutaneous inoculations in guinea-pigs of a small quantity of a pure culture of the bacillus (from one tenth to one half a cubic centimetre of a bouillon culture) caused death in from one to five days. The usual changes observed are an extensive local œdema, with more or less hyperæmia and ecchymosis at the seat of inoculation. Frequently there are swollen and reddened lymphatic glands; increased serous fluid in the peritoneum, pleura, and pericardium; enlarged and hemorrhagic supra-renal capsules; occasionally slightly swollen spleen; sometimes fatty degeneration in the liver, kidney, and myocardium.

"We have always found the Loeffler bacilli at the seat of inoculation, most abundant in a grayish-white fibrino-purulent exudate present at the point of inoculation, and becoming fewer at a distance from this, so that the more remote part of the œdematous fluid does not contain any bacilli" (from Welsh and Abbott). The authors quoted also agree with Loeffler and others in stating that the bacillus is only found at the point of inoculation. In all cases their cultures from the blood and from the various organs gave a negative result, but this is purely negative evidence, and cannot stand as against the positive results of Martin, Behring, and Frosch.

Rabbits are not so susceptible, and may recover after the subcutaneous inoculation of very small doses, but they usually die in from four to twenty days when from two to four cubic centimetres of a bouillon culture have been introduced beneath the skin. In these animals also there is an extensive œdema, enlargement of the neighboring lymphatic glands, and a fatty degeneration of the liver. Roux and Yersin have shown that in these animals, when death does not ensue too quickly, paralysis of the posterior extremities frequently occurs, thus completing the experimental proof of the specific pathogenic power of pure cultures of this bacillus.

Similar symptoms are produced in pigeons by the subcutaneous inoculation of one-half a cubic centimetre or more, but they commonly recover when the quantity is reduced to two-tenths of a centimetre (according to Roux and Yersin).

The rat and the mouse have a remarkable immunity from the effect of this poison, and, according to the authors just spoken of, a dose of two centimetres, which would kill in fifty hours a rabbit weighing three kilogrammes, is without effect upon a mouse that only weighs ten grammes. Old cultures are somewhat less virulent than fresh ones, but when replanted in a fresh culture-medium they manifest their original virulence. Thus a culture upon blood-serum, five months old, was found by Roux and Yersin to kill a guinea-pig in five days, but when replanted, it killed a second animal of the same species in twenty-four hours.

Evidently a micro-organism which destroys the life of a susceptible animal when injected beneath its skin in small quantities, and which, nevertheless, is usually only found in the vicinity of the point of inoculation, must owe its pathogenic power to the formation of a potent toxic substance, which being absorbed gives rise to toxæmia and death.

This inference in the case of the diphtheria bacillus is fully sustained by the results of recent experimental investigations. Roux and Yersin first demonstrated the pathogenic power of cultures which had been filtered through porous porcelain. Old cultures were found by these experimentalists to contain more of the toxic substance than recent ones, and to cause the death of a guinea-pig, in the dose of two centimetres, in less than thirty-four hours. The filtered culture produced in these animals the same effects as those containing bacilli, viz., local œdema, hemorrhagic congestion of the organ, and effusion into the pleural cavities. Somewhat larger doses were fatal to rabbits, and a few drops injected subcutaneously sufficed to kill a small bird within a few hours.

In their second paper, published in 1889, a year after the first, the same authors state that so long as the reaction of a culture in bouillon is acid, its toxic power is comparatively slight, but that in old cultures the reaction is alkaline, and in these the toxic potency is greatly augmented. With such a culture, filtered after having been kept thirty days, a dose of one-eighth of a centimetre injected subcutaneously sufficed to kill a guinea-pig, and in larger amounts it proved to be fatal to dogs when injected directly into the circulation through a vein.

The same authors, in describing the nature of the poison in their filtered cultures, say that it is related to the

diastases, and state that its toxic potency is very much reduced by exposure to a comparatively low temperature (58° C., for two hours), and completely destroyed by the boiling temperature (100° C., for twenty minutes). It was found to be insoluble in alcohol, and the precipitate obtained by adding alcohol to an old culture proved to contain the toxic substance. Loeffler also has obtained, by adding five volumes of alcohol to one of a pure culture, a white precipitate, soluble in water, which killed rabbits in a dose of one-tenth to two-tenths of a gramme when injected beneath the skin of these animals. It gave rise to a local œdema and necrosis of the skin in the vicinity of the point of inoculation, and to hyperæmia of the internal organs. This deadly toxine appears to be an albuminous substance, but its exact chemical composition has not yet been determined.

Brieger and Fraenkel have succeeded in rendering guinea-pigs immune against virulent cultures of the diphtheria bacillus by injecting bouillon cultures three weeks old, which had been sterilized by exposure for an hour to a temperature of from 60° to 70° C., into the subcutaneous tissues; to the amount of from ten to twenty centimetres.

At first the susceptibility of the animal is rather increased than diminished, but at the end of two weeks immunity is said to be complete. Fraenkel is of the opinion that immunity results from the introduction of a substance which is not identical with the toxic product to which the cultures owe their pathogenic power. This latter is destroyed by a temperature of from 55° to 60° C., while the substance which gives immunity is still present in the culture after an exposure to a temperature of from 60° to 70° C., as is shown by the protective results of inoculation made with such cultures.

The recent researches of Behring show that the blood of immune animals contains some substance that neutralizes the toxic product contained in virulent cultures of the diphtheria bacillus. This effect is said to be produced when blood from such an animal is added to a filtered culture without the body as well as when the culture is injected into the living animal. This remarkable fact, if fully confirmed by further investigation, opens up a new field of experimental research, and may lead to important results in the therapeutics of diphtheria and other infectious diseases.

According to Roux and Yersin, attenuated varieties of the diphtheria bacillus may be obtained by cultivating it at a temperature of from 39.5° to 40° C., in a current of air. And these authors suggest that a similar attenuation of pathogenic power may occur in the fauces of convalescents from the disease, and that possibly a similar non-pathogenic bacillus, which has been described by various investigators, has originated in this way from the true diphtheria bacillus.

These authors further state, in favor of this view, that from diphtheritic false membranes preserved by them in a desiccated condition for five months, they obtained numerous colonies of the bacillus in question, but that the cultures were destitute of pathogenic virulence. They say it is then possible, by commencing with a virulent bacillus of diphtheria to obtain artificially a bacillus without virulence, quite similar to the attenuated bacilli which may be obtained from a benign diphtheritic angina, or even from the mouth of certain persons in good health. This microbe, obtained artificially, resembles completely the pseudo-diphtheritic bacillus. Like it, it grows more abundantly at a low temperature; it renders bouillon more rapidly alkaline; it grows with difficulty in the absence of oxygen.

Generalized Occurrence of the Bacillus of Diphtheria.—Frosch (*Zeits. f. Hygiene*, vol. xiii., part 12, p. 49) gives the result of a series of his investigations upon this subject, prefacing them by the remark that the idea seems to have taken a pretty firm hold among observers that the diphtheria bacillus occurs only in those organs where there is a possibility for the formation of membrane, this observation having been made by Babes, Kolisko, and Paltaus and Spronck.

Frosch extended his study over fifteen cases of diphtheria, of which but ten turned out to be true diphtheria, according to the bacteriological examination. Of the remaining five, one was excluded after a critical examination had been made; the second was also excluded because it was impossible to find the bacillus of diphtheria; two of the remaining three proved to be cases of pneumonia produced by a bacillus; and finally the fifth case was found to be one of tonsillitis, characterized by the presence of a new organism that will be described later by him. In the remaining ten cases *the diphtheria bacillus was found in the blood and in the internal organs* in every instance.

After describing the method which he followed in making these observations, Frosch says that in these cases the diphtheria bacilli were found in the brain, the lungs, the liver, the spleen, the kidneys, in the cervical and bronchial lymphatic glands, as well as in the heart, blood, pericardial and pleural fluid, in greater or less numbers. Their occurrence in all of these organs was not uniform, but in all of the cases the bacilli were found in a number of the organs, and, therefore, the observations go to prove that diphtheria may be a generalized disease with only a local manifestation, and that the local manifestation in the throat need not of necessity always be due to the diphtheria bacillus: and finally, that the only way definitely to prove whether the case is one of true diphtheria or no, is the discovery of the bacillus of diphtheria by means of bacteriological examination.

Description of the Pseudo-Diphtheritic Bacillus.—The organism which we are now about to consider is one of great interest, whether it be considered distinct from, or a modified form of, the true bacillus of diphtheria. Loeffler, Von Hoffman, and others have reported finding bacilli which closely resemble the bacillus diphtheriæ, but which differ from it chiefly in being non-pathogenic.

The following account we take from the latest paper upon the subject by Roux and Yersin (their third paper, 1890): Out of 45 children in a Paris hospital, suffering from various non-diphtheritic affections, they found this variety of bacillus in the mucus from the pharynx and tonsils in 15 instances. Out of 59 healthy children in a village school on the seaboard, they found this organism 26 times. Of 6 children with a simple angina, but 2 furnished cultures of this bacillus. Finally, out of 7 cases of measles they found 5 in which they discovered this bacillus. The description which they give of it is as follows:

The colonies of the pseudo-diphtheritic bacillus cultivated on blood-serum are identical with those of the true diphtheria bacillus. At a temperature of from 33° to 35° C. multiplication begins and continues at an ordinary temperature, although slowly. Under the microscope the appearance of the bacillus which forms these colonies is the same as that of the bacillus diphtheriæ. It stains readily with Loeffler's solution of methylene blue, and intensely by Gramm's method. Sometimes it colors uniformly, at other times it appears granular. It grows in alkaline bouillon, leaving a deposit upon the walls of the vessel containing the culture, and in this medium it often presents the "inflated" forms—pear-shaped or club-shaped. It is destroyed in a liquid medium by a temperature of 58° C. maintained for ten minutes. All of these characters are common to the pseudo-diphtheritic bacillus and the true bacillus diphtheriæ. As points of difference between them we may note that the pseudo-diphtheritic bacillus is often shorter in the colonies grown upon blood-serum; that its cultures in bouillon are more abundant; that they continue to grow at a temperature of from 20° to 22° C., at which the true bacillus grows very slowly; finally, that when comparisons of cultures in bouillon are made, it is observed that they both become acid and then alkaline, but that the change occurs much sooner in the case of the pseudo-diphtheritic bacillus. Like the true diphtheritic bacillus, the pseudo-diphtheritic grows in a vacuum, but less abundantly than the other.

Inoculation of animals with cultures of this bacillus has never caused their death, but it is to be noted that

in some experiments a decided œdema has been produced in guinea-pigs at the point of inoculation, while in others there has been no local lesion. The most marked œdema resulted from cultures obtained from cases of measles.

Do the facts that have been reported explain the question which occupies us? Can it be concluded that there is a relation between the two bacilli? On the one side, the presence of the pseudo-diphtheritic bacillus in the mouths of healthy persons, and of those who have angina manifestly not diphtheritic, seems to be opposed to the idea of a relationship between them. On the other hand, when it is considered that the non-virulent bacillus is very rare in cases of diphtheria; that it is more abundant in "benign" diphtheria; that it becomes more common in severe cases as they progress toward recovery; and finally, that they are more numerous in persons who have recently had diphtheria than in healthy persons, it is difficult to accept the idea that the two microbes are entirely distinct. The morphological differences which have been referred to are so slight that they prove nothing. The two micro-organisms can only be distinguished by their action upon animals, but the difference of virulence does not at all correspond with the difference of origin.

As regards the forms and the aspect of cultures the true and the false diphtheria bacilli differ less than virulent anthrax differs from a very attenuated anthrax bacillus originating from the same source. Besides, the sharp distinction which is made between the virulent and non-virulent bacilli is arbitrary. It depends upon the susceptibility of guinea-pigs. If we inoculate animals still more susceptible, there are pseudo-diphtheritic bacilli which must be classed as virulent. If, on the contrary, we substitute rabbits for guinea-pigs in our experiments, there are diphtheritic bacilli which must be called pseudo-diphtheritic. In our experiments we do not simply encounter bacilli which are very virulent, and bacilli which are non-virulent: between these two extremes there are bacilli of every degree of virulence.

Abbott has recently (1891) published the result of his researches with reference to the presence of the pseudo-diphtheritic bacillus in benign throat affections. He made a bacteriological study of 53 patients, 9 of whom were suffering from acute pharyngitis, 14 from acute follicular tonsillitis, 8 from ordinary post-nasal catarrh, 2 from simple enlarged tonsils, 15 from chronic pharyngitis, 1 from subacute laryngitis, 1 from chronic laryngitis, 1 from rhinitis, and 2 from an affection of the tonsils and pharynx. In 49 cases nothing of particular interest was observed. A variety of micro-organisms were isolated, and of these the pyogenic micrococci were the most common. In four cases micro-organisms were found which resembled the bacillus diphtheriæ of Loeffler in their morphology and growth in the culture-media, but which proved not to be pathogenic. Abbott says the single point of distinction that can be made out between the organism obtained in three of his cases and the true bacillus of diphtheria is in the absence of pathogenic properties from the former; whereas, in addition to this point of distinction, the organism from a fourth case gives, as he states, a decided and distinct growth upon the surface of sterilized potato.

Experiments have been made which tend to show that diphtheria, as it is observed in the lower animals, is not the same thing as the diphtheria which affects man. It has been found that there are distinct varieties of bacteria in these different forms of diphtheria. Descriptions of these will now be given.

The Bacillus Diphtheriæ Columbarum.—This was described in 1884 by Loeffler, who obtained it from diphtheritic pseudo-membranes in the mouths of pigeons dead of a form of diphtheria which prevailed in some parts of Germany among these birds, and among chickens. Reddened patches first appear upon the mucous membrane of the mouth and fauces, and these are covered later with a rather thick yellowish layer of fibrinous exudate. In pigeons, the back part of the tongue, the fauces, and the corners of the mouth are especially affected; in chickens, the tongue, the gums, the nares, the laryux, and the conjunctival mucous membrane.

The disease is especially fatal among chickens—the young, and those of choice varieties being most susceptible. It is attended at the outset by fever, and usually proves fatal within two or three weeks, but may last for several months.

Morphology.—They are short bacilli, with rounded ends, usually associated in irregular masses, and resembling the bacilli of rabbit septicæmia, but a little longer and not quite so broad. In sections from the liver they are seen in irregular groups in the interior of the vessels. It is an aërobic, non-motile, non-liquefying bacillus. It grows in nutrient gelatine in the form of spherical white colonies along the line of puncture, and upon the surface it has a whitish layer. Under the microscope the colonies in gelatine plates have a yellowish-brown color and a slightly granular surface. Upon blood-serum the growth consists of a semi-transparent grayish-white layer; upon potato a thin layer is formed having a grayish tint.

Pathogenesis.—Pigeons inoculated with a pure culture in the mucous membrane of the mouth are affected exactly as are those which acquire the disease naturally.

Subcutaneous inoculation in pigeons gives rise to an inflammation resulting in local necrotic changes.

Pathogenesis for Rabbits and for Mice.—Subcutaneous injections in mice give rise to a fatal result in about five days. The bacillus is found in the blood and in the various organs, in the interior of the vessels, and sometimes in the interior of the leucocytes, and they are especially numerous in the liver. The lungs are dotted with red spots; the spleen is greatly enlarged, and the liver has a marbled appearance from the presence of numerous irregular white masses scattered through the pale red parenchyma of the organ. These white masses are seen in sections to consist of necrotic liver tissue, in the centre of which the bacilli are found in great numbers, in the interior of the vessels. This appearance is so characteristic that Loeffler considers inoculation in mice to be the most reliable method of establishing the identity of the bacillus. It is not pathogenic for chickens, guinea-pigs, rats, or dogs. There seems to be some doubt whether the form of diphtheria which prevails among pigeons, and which Loeffler has shown to be due to the bacillus above described, is identical with the diphtheria of chickens. Diphtheria in man has been supposed by some authors to be identical with that which prevails among fowls, and, possibly, this may be the case, under certain circumstances. But the evidence seems to be convincing that there is an infectious diphtheria of fowls which is peculiar to them, and which, under ordinary circumstances, is not communicated to man.

The Bacillus Diphtheriæ Vitulorum.—This was described by Loeffler in 1884, and was obtained by him from the pseudo-membranous exudation in the mouths of calves suffering from an infectious form of diphtheria.

The disease is characterized by the appearance of yellow patches upon the mucous membranes of the cheeks, the tongue, and sometimes the larynx and nares of infected animals. There is a yellowish discharge from the nose, an abundant flow of saliva, occasional attacks of coughing and diarrhœa. Death may occur at the end of four or five days, but usually the animal survives for several weeks. Diphtheritic patches, similar to those in the mouth, are also found in the large intestine, and there are scattered abscesses in the lungs. Loeffler, in a series of seven cases examined, obtained from the deep portion of the pseudo-membranous deposit a long bacillus which appeared to be the cause of the disease.

Morphology.—They are bacilli five to six times as long as they are broad, usually united in long filaments. The diameter of the rod is about half that of the bacillus of malignant œdema.

Biological Characters.—Attempts to cultivate this bacillus in nutrient gelatine, blood-serum from sheep, and various other media, were unsuccessful. But when fragments of tissue containing the bacillus were placed in blood-serum from the calf, a white border consisting

of the long bacilli was developed. These could not, however, be made to grow when transferred to fresh blood-serum.

Pathogenesis.—Mice inoculated subcutaneously with the fresh diphtheritic exudation died in from seven to thirty days. The autopsy disclosed an extensive infiltration of the entire walls of the abdomen, which often penetrated the peritoneal cavity and enveloped the liver, the kidneys, and the intestines in a yellowish exudate. The bacillus was found in this exudate, and by inoculating a little of it into another animal of the same species a similar result was obtained. It is not pathogenic for rabbits or guinea-pigs.

The Bacillus of Intestinal Diphtheria in Rabbits.—This was described by Ribbert, in 1887, and was obtained by him from the organs of rabbits which had an affection characterized by a diphtheritic inflammation of the mucous membrane of the intestines. The autopsy revealed, also, swelling of the mesenteric gland, and minute necrotic foci in the liver and spleen.

Morphology.—Bacilli with slightly rounded ends, from three to four micromiltimetres long and from one to one and four-tenths micromillimetre in diameter. Often united in pairs or in filaments containing several elements. Stain with the usual aniline colors, but not so readily in sections as do some other bacteria.

Ribbert recommends staining with aniline-water, fuchsine solution, washing in water, then placing the section in methylene blue solution and decolorizing in alcohol. The bacilli cannot be stained by Gramm's method.

Biological Character.—It is an aërobic, non-liquefying bacillus. The question of its motility is not yet settled. Upon gelatine plates semi-transparent, grayish colonies are formed, which later turn a brownish color. The surface of these is finely granular and of a pearly lustre. In needle cultures in nutrient gelatine the growth along the line of puncture is very scanty. On potato a flat, whitish layer is formed which extends slowly over the surface. It grows best at a temperature of from 30° to 35° C.

Pathogenesis.—Pure cultures injected into the peritoneal cavity, or subcutaneously, in rabbits cause the death of these animals in from three to fourteen days, according to the quantity used. At the autopsy necrotic foci are found in the liver and spleen and the mesenteric glands are enlarged, but the intestines present a healthy appearance; but when cultures are introduced into the alimentary canal the characteristic diphtheritic inflammation of the mucous membrane of the intestines is produced. This result was obtained both by direct injection into the interior of the intestines and by injecting cultures into the mouth.

Diagnosis.

The characteristic sign of diphtheria is the presence of a circumscribed membrane with more or less congestion of the surrounding parts. The fever is not always a prominent symptom, and but little importance can be attached to it. High fever at the beginning of the disease should make the diagnosis doubtful for the time. Swelling of the glands of the neck, especially about the angle of the jaw, is an important aid in the diagnosis. The absence of this sign is, however, of no weight as negative evidence. It is of especial value when the process is seated in the nose, and its exact location cannot be readily ascertained.

Diphtheria of the vagina and conjunctiva and of wounds can only be confounded with a simple purulent coating where ocular examination alone is at command: confusion between the two processes can very seldom occur. The eruption, when it is present, occurs about the chest, neck, and abdomen, and is to be distinguished from that of scarlatina, according to Jacobi, in that this latter first appears about the hips and extremities. Not infrequently, however, the differential diagnosis is extremely difficult, and can be made only after sufficient time for observation of the efflorescence has elapsed. Albuminuria, if present in the first few days of attack, is an indication of diphtheria; if it appears later, of scarlatina. The diagnosis of diphtheritic paralysis presents no difficulties if the case has been watched from the beginning and the diagnosis of the primary disease has been satisfactorily made.

The settlement of the question as to whether a paresis is a sequel of diphtheria or not, is often impossible if the previous history be obscure. The special characteristics of the diphtheritic paralysis are, that it very frequently starts from the pharynx; that its course is exceedingly irregular; and that it is mostly peripheral in character, generally motor, and sometimes sensory.

Differential Diagnosis.—Diphtheria may be confounded with scarlet fever, confluent herpes of the throat, acute tonsillitis, and acute laryngitis.

In addition to the points already touched upon, the following aids to diagnosis may be mentioned:

The disease may be differentiated from scarlet fever by a consideration of the following facts: In scarlet fever there is less constitutional disturbance; the throat is less uniformly reddened; the membrane, if any exists at all, is more easily detached; and the larynx is almost never attacked; but, on the other hand, hæmaturia is common, while it is rare in diphtheria. The rash is different in the two diseases. In diphtheria it is not commonly present; it appears at irregular periods, is partial, appears suddenly in patches, and is of an uniform erythematous redness, without the punctated appearance peculiar to the scarlatinal eruption (Meigs and Pepper).

It is very often impossible to differentiate acute tonsillitis from diphtheria at first. If the case be one of tonsillitis, however, the inflammation either subsides or suppuration occurs, which at once makes the diagnosis plain. In such cases aid must be sought from the bacteriological examination. Confluent herpes has the peculiarity of a rapid rise in temperature, followed by an equally rapid fall. The pain in the throat is of a peculiar smarting character, and there is no tendency to spread. The presence of herpes of the lips is often of very great help in making out the diagnosis. Catarrhal laryngitis of a severe form is oftentimes impossible to differentiate from diphtheria, especially in the early stages. When the disease is fully developed it is easier to distinguish it correctly, for catarrhal laryngitis nearly always ends in recovery and without the severe sequelæ of diphtheria.

Recent investigations show that it is not possible to make a certain diagnosis of diphtheria excepting by the bacteriological examination; the discovery of the true bacillus of diphtheria, in material taken from the suspected spots of inflammatory reaction, settles the question.

That there are other throat affections very closely resembling, from a clinical point of view, true diphtheria, is unquestionable, and in this connection the work of Martin (to be found in the *Annales de l'Inst. Pasteur*, May, 1892, p. 335) is of very great interest. In this article the author reports that he has made both a clinical and a bacteriological examination of two hundred children who were sent into the diphtheria ward with a clinical diagnosis of diphtheria. The very full extracts that we shall give from this article are justified by the extreme importance of the subject.

He says that when a child arrives at the hospital, it is likely to present one of these two different conditions, viz.: 1. There may be a white angina, with or without laryngeal trouble; or, 2. there may be no visible false membrane, the child presenting only the symptoms of a laryngitis; in other words, as the parents say, it has the croup.

The rapid examinations to which these patients are submitted are necessarily inconclusive, but usually, as a result, they are sent into the diphtheria ward.

In order to arrive at a certain diagnosis, bacteriology, according to this author, now furnishes two methods of procedure, first, the examination of the false membrane, and second, cultivation upon coagulated serum and examination of the cultures after twenty-four hours.

1. *The Direct Examination of the False Membrane.*—This examination was made after the method of Roux and Yersin (in the *Annales de l'Inst. Pasteur*, 1890), and in many cases it was possible to discover at once a bacil-

lus of diphtheria, thus facilitating the making of a rapid diagnosis. This, however, was not always practicable, much care and great expertness being required for such work; many preparations had to be examined, and it had to be definitely determined that the bacillus seen stained well according to Gramm's method. Very often it is exceedingly difficult to recognize the bacillus of diphtheria among a great number of other bacteria, and when it is not discovered it is not permissible to say that the case is not one of diphtheria.

2. *Cultivations from the Suspected Spots.*—In certain cases of croup without false membranes the microscopic examination of the mucus of the posterior portions of the throat, spread out upon a cover-glass and colored with methyleue blue, did not permit a definite diagnosis, and at the same time this same mucus sowed upon serum gave very numerous colonies of the bacilli of diphtheria.

The best method is to *always* use coagulated serum, which is a medium that is very favorable for the development of the bacillus of diphtheria, and upon which it develops in a few hours, before any—or at any rate most—of the other bacteria of the mouth.

The culture is to be taken directly from the throat with a platinum needle flattened into the shape of a spatula at the end; the false membranes, when they exist, are to be touched, or simply the mucus in the apparently simple cases of laryngitis without false membrane; then the spatula is drawn over two or three tubes of serum without retouching the throat. The tubes are then to be placed for twenty-four hours in a thermostat at 37° C., and, if it be a case of true diphtheria, numerous colonies will soon appear, especially upon the first tubes that were inoculated; even after the lapse of eighteen hours they can be recognized and examined, and it was never found necessary for the author to wait more than twenty-four hours. After a longer time than this the other bacteria commenced to develop and rendered the diagnosis more difficult. In cases of severe diphtheria the colonies of the bacillus of Loeffler are more numerous than in mild cases. In certain anginas that were not diphtheritic no colonies developed during the first twenty-four hours. The presence of a great number of colonies upon the tubes make probable the diagnosis of diphtheria, especially if this occurs soon; but there are certain anginas produced by a coccus that also gives numerous colonies after the lapse of twenty-four hours, upon inoculation upon blood-serum. In the latter case the microscopic examination will determine the truth and render all confusion impossible.

Upon the serum the colonies of the diphtheria-bacillus are round and very regular, of a yellowish-white color, and more opaque in their centre by transmitted light; as they grow older they increase in size, remain regular, and become sometimes of a pale yellow color. Certain cocci give, also, colonies resembling those of diphtheria, but their surface is more moist, while their centre is not thicker than the edges.

The colonies of the streptococci are still very small at the end of twenty-four hours, and it is not possible to confound them with those of the bacillus of diphtheria, which are at least six or seven times as large. Colonies of the staphylococcus aureus have also been found, as well as other bacteria that liquefy the serum. These colonies develop especially after twenty-four hours, and do not trouble the observer. In the entire observation only those colonies need be considered that develop upon serum, and this is the only nutrient medium that it is at all necessary to employ.

When the diphtheria colonies were in a great majority, the cases were regarded as pure diphtheria; but if with the bacillus of diphtheria numerous colonies of different species were found, then the bacteria mixed in the secretions were considered. Those most often associated with the bacillus of diphtheria were micrococci and streptococci, their presence seeming to have an influence upon the progress of the disease, and furnishing, also, a basis for a prognosis.

The author claims that the examination of the number and of the form of the colonies is only a preparatory work, and must be followed by the microscopical examination, which shows that the bacillus of diphtheria does not always present itself under the same form. He distinguishes three varieties: (1) Long bacilli, which are the typical organisms of diphtheria described by all the authors; there are also (2) small bacilli that are placed side by side, and appear thicker than the ordinary bacilli, because they are shorter; and finally, between these two, there is (3) an intermediate form of bacillus of a medium length, the individuals of which are also placed side by side. The colonies of these three forms are not distinguishable upon serum, although the short bacilli often give whiter, more moist colonies, which continue to increase, even outside of the thermostat, and answer very closely the description given by Loeffler of the pseudo-diphtheritic bacillus.

From the point of view of virulence there are differences between these bacilli of different forms, but they are considered to be, all of them, bacilli of diphtheria. Martin found the short bacilli very mild in their action, the medium-sized bacilli a little more toxic, while the long bacilli are the most infectious. Among a number of cases of diphtheria which he had verified by bacteriological examination there were several fatal ones in which the short bacilli were found, but these were always associated with the streptococci; and often, in cases of measles with sore throat, were found the short bacilli, which, although mild under ordinary conditions, seemed, in these particular cases, to take on more virulent properties.

The author, in discussing further the question of diphtheria, lays especial stress upon what appears to be an exceedingly important point, particularly in the light of the investigation of Frosch, already quoted in this article. He says, that at autopsies he often looked for the bacilli of diphtheria in the respiratory tract, especially in the pulmonary parenchyma, and that he very often succeeded in finding them in these places. In all cases there was an inflammation of the lungs, which appeared under the form of a lobular broncho-pneumonia. Many times it was in the lungs that the greatest quantity of the bacilli was found, and in these observations there was no false membrane in the throat and very little in the trachea. It appeared to be the pulmonary parenchyma that was the principal seat of the infection. It even appeared to him, in certain cases, that *the lungs were primarily attacked*, and that the trachea and the larynx were only the *secondary* seats of the disease.

By this study of two hundred cases of supposed diphtheria it has been established that there are in reality three great classes of disease: the non-diphtheritic anginas, of which there were forty-three cases; the diphtheritic anginas of which there were sixty-nine cases; and croup, of which there were eighty-eight cases. In other words, *forty-three cases had been sent to the diphtheria ward that did not have diphtheria at all.* Among these cases four were attacked with measles. This point alone emphasizes, more than anything well could, the extreme importance of a correct differential diagnosis, and that this diagnosis should be made before the patient is sent in to the diphtheria ward. In other words, every hospital should have a detention-room or observation ward, in which suspected cases of diphtheria should be detained long enough to determine whether or not they be cases of true diphtheria, and whether, as a consequence, they should or should not be sent to the diphtheria ward. There can be no doubt but that this is a matter of very great importance.

More remarkable still is the observation that out of these forty-three cases thirty-six, in which it was not possible to determine the presence of the diphtheria bacillus, showed the occurrence of false membranes in some portions of the throat. There were, therefore, this number of clinical errors in diagnosis, and the sufferers were put in jeopardy of their lives by reason of the omission of this extremely important point in diagnosis.

The non-diphtheritic cases are divided into angina produced by micrococci—the most common of these occurring in the form of a diplococcus, which has already been

described by Roux and Yersin, and which is found in immense numbers in the false membrane, where it appears in places as a pure culture. This diplococcus is to be regarded as the cause of the process. If we sow the cocci taken from one of the false membranes which they have produced, upon serum, there will be developed, in less than twenty-four hours, non-liquefying colonies that are as numerous and as pure as the colonies of the true diphtheria-bacillus obtained from typical cases. Upon a superficial examination these colonies appear to resemble those of diphtheria, but they are more moist and more transparent. Loeffler's methylene blue easily stains the coccus, which also stains by the method of Gramm, and it can also be cultivated upon nutrient agar. The false membranes produced by the activity of this organism resemble so closely true diphtheritic membranes that they are almost invariably regarded as such. Like the latter, they are reformed very quickly if they be torn away.

The progress of the cases is characterized by the exhibition of extreme prostration, and a marked characteristic of these false membranes is their tendency to recurrence. The sore throats produced by this coccus do not as a rule terminate fatally; they generally become better very rapidly and leave no evidences of systemic poisoning behind them.

A second class of non-diphtheritic cases owe their origin to the presence of streptococci. The streptococcus pyogenes is an organism which is very commonly found in the mouth, and which can produce alterations of the mucous membrane resulting in fibrinous exudation and the formation of pseudo-membranes. A number of observers have seen this occur, notably Prudden, who worked upon cases of apparent diphtheria produced by this streptococcus, and confounded these cases with those of true diphtheria. Cases produced by this streptococcus are not virulent any more than are those of the preceding coccus, at least to anything like the same degree as the cases resulting from the activity of the true diphtheria bacillus.

The second class into which the 200 cases are divided is that of diphtheritic anginas without croup. Of these there were 62 cases of pure diphtheritic anginas, following out the ordinary clinical history of cases of diphtheria. Of the remainder, some of the cases were diphtheritic anginas mixed with the streptococci, and diphtheritic anginas mixed with the micrococci. The general history of these tended to show that a mixed infection produces a *milder form of diphtheria* than when the diphtheria bacillus is present by itself.

Another division of the cases was into croup—croup with false membranes—of which there were 54 cases, and of these there were 17 cases which were shown to be non-diphtheritic, and 13 cases of diphtheritic croup with mixed bacterial infection—some of them with the streptococcus and some with the coccus alone. And then there were cases of pure diphtheritic angina accompanying croup. Finally, the last division of cases is that of croup without false membrane in the throat; and of these there were 34, 21 of which were proved to be diphtheritic, while 12 were not.

The author, in concluding his work, says that his first object in undertaking it had been to find out how far bacteriology could aid the clinician in the diagnosis of diphtheria; and he makes the statement, which can scarcely be disputed, that the most accurate clinician is deceived once out of five times—whether it be in the direction of mistaking a non-diphtheritic angina for diphtheria, or in that of not recognizing a case of true diphtheria. Bacteriological researches have furnished many extremely interesting and important points bearing upon the clinical and bacteriological history of the pseudo-membranous anginas that are non-diphtheritic. Bacteria play an exceedingly important part in affections of the throat, and it is bacteriology alone that can clear up the question of the anginas, for their clinical characteristics are entirely insufficient to distinguish them.

As a conclusion to this remarkable and important paper the author makes the following statements:

Many anginas with false membranes, and, also, many cases of croup, are confounded with diphtheria. Bacteriological examination furnishes the most certain and the most rapid means for making the exact diagnosis of diphtheria. There are pure diphtherias and diphtherias associated with other bacterial infections, and among the latter—the diphtherias with other bacteria—those in which the streptococci are found are the most severe, while those in which the micrococci are found are the most benign. The temperature curve furnishes an excellent method for determining the prognosis, and upon this point the author has laid very great stress, instancing many cases (accompanied by reproductions of charts) in which a study of the temperature observations, made at the same hour morning and night, revealed the fact that there appeared to be a curve almost as characteristic for diphtheria as that which is usually supposed to belong to typhoid fever.

In a recent number of the *Philadelphia Medical News* (December 10, 1892) Wyatt Johnston, of Montreal, makes a suggestion for the ready diagnosis of diphtheria that seems to be entirely practicable. It consists in boiling an egg hard, which, of course, solidifies the albuminous contents, and, at the same time, sterilizes the shell. There is prepared at the same time an ordinary egg-cup, which may be sterilized by burning a little alcohol in its hollow. A small portion of the shell of the egg is then chipped off at one end, and a minute portion of material from the throat of the suspected case is drawn over it with a platinum needle, three or four separate times, without retouching the platinum needle to the throat, and the egg is then inverted in the egg-cup and the whole placed in a warm place over-night. By this means it is often possible to make a perfectly satisfactory diagnosis of diphtheria in a comparatively short time, and with the simplest form of apparatus. For if the diphtheria bacillus is present it will grow rapidly upon this solidified egg-albumen, and the characteristic colonies will be present upon the following morning, when the diagnosis may be further verified by microscopic examinations of the colonies that have made their appearance. Park, in a recent number of the *Medical Record* (February 11, 1893), expresses some doubt in regard to the trustworthiness of the method just described.

Among those who have expressed themselves strongly in regard to the importance of resorting to bacteriological examinations in making a diagnosis of diphtheria may be mentioned Martin, from whose paper we have already given very full extracts; Park (*Medical Record*, July 30 and August 5, 1892, and February 11, 1893); Baginsky (*Berliner klin. Wochenschr.*, February 29, 1892); and Koplik (*New York Medical Journal*, August 25, 1892). There is doubt whether in the course of time clinical features will be discovered by means of which true diphtheria can be distinguished from the forms of disease which resemble it.

Prognosis.

The prognosis in each individual case should be very guarded. To assume that recovery is probable, before the disease has run its course, is exceedingly unsafe, and even then relapses may occur and the result be once more placed in doubt. The general course of an epidemic may have some influence upon prognosis, but that influence is exceedingly small, for it is the mild cases that are often the most deceptive. Speaking very generally, the prognosis is favorable where the local manifestation of the disease is of small extent and is situated on a part that has but little communication, by way of the lymphatics, with the rest of the system. An indication of sluggishness in the course of the disease, as in diphtheria of the womb or the angles of the mouth, is unfavorable, as is also the extension of the disease to the larynx. The septic or gangrenous forms of diphtheria are especially dangerous, but the elevation of the body temperature has not been thought to have any particular bearing on the final result. Martin, however (*loc. cit.*), lays great stress upon the temperature curve as a guide in prognosis. A rapid, small, and irregular pulse is a sign of failure of the heart, but is not a very bad sign so long

as there is an approximately normal relation between it and the rate of respiration. Every complication adds to the gravity of the prognosis. During convalescence the extension of the paralysis to the muscles of respiration is a very alarming sign. The indications of immediate danger are croupy symptoms arising from the extension of the membrane into the larynx, a brown or black appearance of the false membrane, a hemorrhage from the nose, throat, bronchi, or intestines, copious discharge from the nostrils, intense albuminuria, great swelling of the cervical glands, decided fall of temperature, and nausea or diarrhœa at an advanced period of the disease. Any one of these may occur without being necessarily fatal, but two or more mean extreme danger.

Treatment.

There is no specific for diphtheria. Treatment is to be based, first, upon general principles, and, second, upon local applications. Measures to sustain the general health are of the greatest importance, and should receive special attention. The room should have a temperature of from 62° to 65° F.; it should also have, if possible, a sunny exposure, and there should be an open fire. The diet should be very nutritious, consisting of beef-tea, milk, and the like, given regularly in small quantities and at short intervals, especially during the night, for it is then that the vital powers are in their least resistant state.

If signs of failure of the heart appear, the patient's head should be kept as low as possible. High fever should be treated with sponge-baths of tepid water; quinine and salicylate of sodium are also recommended. Collapse should be met with the free exhibition of stimulants, and severe vomiting or diarrhœa should be checked at once. Quinine and the method of employing it should be left to the judgment of the physician. As complete isolation of the case as is possible should be practised; the sick-room should be kept cool (the temperature spoken of above is the best), and plenty of fresh air should be admitted. The nurses should keep the mouth closed when over the patient, and any caressing or fondling should be absolutely prohibited. It is also a good plan to wear cotton in the nostrils as a filter.

The general treatment should be begun early, as there is no typical course to the disease, and, therefore, delay is dangerous. There is small chance of giving too much stimulant, and a tonic never does harm, whereas its omission may be seriously felt.

An exceedingly important measure is the disinfection of the room, and of all objects which may have come in contact, in any way, with the patient. In the case of a room this may (?) be effected by fumigation; two pounds of rolled sulphur to every seventeen hundred and twenty-eight cubic feet of space being burned for this purpose. A copperas solution, one and a half pound to a gallon of water, may be used for everything that can be placed in it. Better than this is a solution of corrosive sublimate (one part to ten thousand of water) which should be freely used in all drains, privies, and so on, and for soaking all soiled linen or clothing.

The instructions given for disinfection by the National Board of Health, Bulletin No. 10, September 6, 1879, are simple and effective, provided the corrosive sublimate solution be substituted for the other agents mentioned. Best of all, however, is prolonged boiling of all infected material.

The infectious agent is confined, as we know, to the affected area, and in diphtheria of the mouth and air-passages, it will be found only in these situations or in material coming from them. The spread of infection should therefore be a comparatively easy matter. All saliva, mucus, blood, etc., coming from the patient, should be received upon towels or old rags that may be at once folded inward and subjected to boiling for at least half an hour. The same treatment should be given to the bed-clothing of the patients. Spoons and other articles coming in direct contact with the affected parts should be dropped *at once* into a vessel containing water, and then also boiled as in the case of the other articles. Nurses and other attendants may avoid infection, themselves, or the danger of carrying it in their clothing, if they put on a loose gown, tight at the wrists and neck, at the entrance to the sick room, and remove this article of dress immediately upon leaving the room. The hands should *at once* be thoroughly cleansed by soap and water as hot as can be borne.

The *special precautions* that are needed in the case of diphtheria of the air-passages, for the safety of the observer, are to avoid inhalation of the breath of the patient, and this especially at the time of coughing. The infectious material of diphtheria is so well known now, its localization is so defined, and at the same time so limited, that there should be no especial danger in the future of its being transported.

Special Treatment.—There is, at present, no specific for diphtheria. The first indications are to employ those remedies which have, or seem to have, an effect in softening or destroying the false membrane. The principal among these are steam inhalations, which have been employed in various ways, as from the nozzle of a kettle and by dropping hot bricks into water. The best method of employment is by means of the atomizer, used very frequently in conjunction with some therapeutic agent, such as carbolic acid, salicylic acid, salt, or chlorate of potassium. This latter remedy is one very widely employed and of especial benefit—not, however, as a specific against the disease. Its beneficial effects arise from its alleviating the laryngitis and stomatitis accompanying the disease, and from its placing the surrounding parts in such a condition that the false membrane rarely spreads. It should be given freely, that is, in small doses and frequently. One of the best methods of application is by the steam atomizer;—using the spray for five or ten minutes every hour has been followed by the most successful results. The strength of the solution to be used is that of saturation; a sufficient dilution for safety being effected by the steam. For children the solution should be weakened so that a child of three years will not get more than twenty grains in the twenty-four hours. Serious results, such as acute nephritis, have been recorded from overdoses of this drug, but properly employed its great value is unquestionable. It does not have any marked effect in dissolving the diphtheritic membrane, as has been supposed.

Steam is of value only in those cases in which the membrane is upon the surface. Water, to promote the secretions, is of value, either given alone or combined in hot drinks of various kinds. Cold water and cold applications in the form of ice-bags are useful in many ways in easing the discomfort of the swollen and sore throat. Cracked ice, water ices, and ice-cream, give relief. Sponging with tepid water when the body temperature is high, and the skin hot and parched in consequence, gives great comfort to the patient. If there are signs of a weakened circulation, however, this remedy is contraindicated. Lime-water, either alone or in combination with glycerine, applied locally to the throat by means of spraying, sponges, or gargles, has been very highly thought of as exerting some solvent effect upon the membrane. The action is so slow, however, that the good results obtained are probably due, as suggested when speaking of chlorate of potash, more to their cleansing effects than to any specific action; and the same is probably true of acetic acid and other well-known remedies.

Peroxide of hydrogen is one of the more recent and highly endorsed remedies in the treatment of diphtheria. I have obtained good results, apparently, from the use of the following formula:

℞. Acid. sulphuros. dil.	.....	♏ x.–xxx.
Tinct. ferri chlor.	.....	ʒ v.
Syrup. aurant. cort.	.....	℥ jss.
Aq. dest	.....	℥ ijss.

M. Sig.: Half a teaspoonful to a teaspoonful in a tablespoonful of water.

This may be repeated every two to four hours, and should be given through a glass tube.

Inhalations of the oil of turpentine are recommended to be administered for ten or fifteen minutes every hour. A better method of employment is by boiling some water, containing half an ounce of the spirits of turpentine, in the room. This should be kept going continuously,

Chloride of ammonium seems to be of use occasionally. Dose, internally, from one to two grains every two or three hours, for a child of two years; or half a drachm to be burned over a flame in the room.

Mercury has been extensively used, and is very strongly supported by Jacobi, of New York.

Astringents, such as alum, tannin, nitrate of silver, have almost entirely passed out of use; their employment seeming to retard, rather than to favor, the subsidence of the exudative process.

Chloride of iron, introduced by Gigot, in France, in 1848, has been used very extensively and beneficially, if given freely and at frequent intervals. As much as from five to ten drops of the tincture every half hour may be given.

Carbolic acid is helpful merely as a cleansing agent, and perhaps not even for that. Ozone has been recommended, with no very great results from its employment.

Salicylic acid, quinine, potassa fusa, and other strong salts, bromine, and so on, are among the remedies that have been proposed. Boric acid solution (one to thirty), used as a gargle, and benzoate of sodium (one to eighteen parts of water), are among the other remedies that have been proposed. Sulphur and cubebs (used in capsules) nearly complete the list of remedies.

Gargles, sprays, and local applications of watery solutions of corrosive sublimate (varying from one in three thousand to even greater strengths) have also been employed.

Mechanical removal of the membranes must not be practised. When these can be detached without force they will come off of themselves, and this time should be patiently awaited.

Swelling of the lymphatic glands in diphtheria must be treated as if an idiopathic affection, by applications of cold water or ice compresses, and, if absolutely necessary, by incision.

Nasal diphtheria must be combated by the assiduous use of douches composed of some of the remedies spoken of above; they should be used every hour.

Laryngeal diphtheria is occasionally helped by the employment of emetics. It is when the symptoms become urgent, in this form of disease, that tracheotomy is resorted to; the indications for the operation being the danger of suffocation from stenosis of the larynx. The mortality after the operation increases in proportion to the delay in its performance.

As a substitute for tracheotomy in stenosis of the larynx in diphtheria, the famous procedure of intubation has been very widely employed. The success attending this substitute for the cutting operation has not been so great as was hoped at first; doubts of its effectiveness in practice have increased very much of late. Farther on in this volume, under its appropriate heading, will be found a fresh contribution to the subject of intubation, by the inventor of the procedure, Dr. Joseph O'Dwyer, of New York. The reader is referred to this for additional information on the subject.

Diphtheritic paralysis may in many cases be treated simply by rest, good food, stimulants, tonics, such as iron and quinine, and sometimes by electricity. Strychnia is recommended, but its usefulness is very doubtful.

Diphtheritic conjunctivitis must be attacked at once, and vigorously, with ice applied locally, and boric acid in concentrated watery solution, every hour. The uninfected eye must be carefully protected from inoculation, and this is best done by covering it with lint and collodion, or with lint, cotton, and adhesive plaster.

General Investigations for Methods of Treatment by Bacteriological Research.—In order to understand clearly the attempts which have been made to obtain something in the way of a cure for diphtheria by bacteriological methods, a statement should be made of the general way in which immunity and cure, in infectious diseases, has been sought by different observers, along bacteriological lines. These methods are well summarized by Behring in the tables given by him in the first part of his work upon "Blood-serum Therapeutics," published in Leipzig, 1892. In this first part he gives three tables:

Table I. A Method of Obtaining Immunity against Infectious Disease.—A. *Immunity with the help of disease-producing materials, similar to those against which immunity is sought.*

1. The Attenuation Method (Pasteur's method; Vaccination). Of general applicability. (*a*) Immunity by the employment of attenuated cultures of living bacteria. (*b*) Immunity by attenuated poisons. In both of these cases one has the choice of producing the attenuated material by the following methods: (a) Attenuation by high temperature; (b) attenuation by low temperature; (c) attenuation by means of chemical agents; (d) attenuation by atmospheric influences, especially insolation.

2. The method by dilution. Of limited applicability. Consists in the employment of (*a*) cultures of full virulence, (*b*) culture-fluids of full toxicity.

3. The combined method (Behring's method). Of general applicability. Consists in the obtaining of immunity by the help of the attenuation method first, and then following it by the employment of cultures of full virulence and full toxicity in order to obtain a very high degree of immunity.

B. *Obtaining immunity by the help of disease-producing materials of a different kind from those against which immunity is sought.*

1. The employment of living bacteria cultures, or of specific chemical materials which are contained in it.

2. The employment of chemical preparations.

3. The obtaining of immunity by the direct transference of the immunity-containing agent. This is Behring's blood-serum therapeutics.

Table II. The Method of Action of the Agent Producing Immunity.—1. By the destruction of the living cause of the disease.

2. By hindering the growth of this living cause.

3. By the destruction of its infectious properties, which result, according to Behring, is effected by taking away from the bacteria their power of producing their poisonous products.

4. By the destruction in the infected organism of the poisonous material produced there.

5. By such a change of the central organs, or of the living cells, that they obtain a higher degree of resisting power against the nerve toxines and cell toxines produced by the bacteria.

Table III. Conditions Necessary for the Production of Immunity.—A. *A passive state of the organism* (the exhaustion theory, and the theory of non-favorable culture media).

B. *A functional condition of the organism,* divided into: 1, A function of the living condition of the organism (the contest theory); 2, a function of the dead condition of the organism.

These three tables give a very accurate view of the various theories upon which experimental work has been based in order to secure immunity from, or cure of, infectious diseases.

Of all these the one which has been especially applied to the study of diphtheria, is that of Behring, marked (c) in Table I., and is included in what Behring has called "blood-serum therapeutics."

The history of the investigations which have been made in the domain of diphtheria is exceedingly interesting. The first paper that appeared on the subject was by Behring and Kitasato, in 1890 (in No. 49 of the *Deut. Med. Wochenschrift*); the second was by the same authors in the same year (No. 50 of the same journal); the third was by Boer (a monograph upon the methods of treating guinea-pigs infected with diphtheria with chemical preparations); and the fourth was by Behring and Wernicke, in 1892 (*Zeitschrift f. Hyg.*, 1892, vol. xi.), upon

the immunity and cure of animals affected with diphtheria. The result of all this work is to furnish a promise of something of great value in the future. Certainly great results have been obtained by similar work in the domain of tetanus in man, and the outlook for something really satisfactory in the domain of diphtheria is very promising.

The theory acted upon in the production of immunity against diphtheria may be best explained as follows: It is a long time since the theory that immunity might be due to the presence of a deterrent substance in the blood entered the mind of scientific men,—this substance being something that would prevent the growth of the invading bacteria or prevent the development of their toxic poison; but it has been an exceedingly difficult matter to secure evidence upon the point.

The first experimental researches were negative (those of Grawitz and Gamaleia), but in 1884 Grohmann showed that fresh serum exerted an attenuating influence upon the bacilli of symptomatic anthrax. Fodor found that fresh blood destroyed them, while Nuttall established the fact that organic fluids, blood-serum, aqueous humor, pericardial fluid, etc., really possessed the power of destroying bacteria, and that this germicidal action was taken away by raising these fluids to a temperature of about 60° C. Buchner showed that this power rested solely in the serum, and that the breaking up or mixing in of the blood-corpuscles masked or diminished its activity. He also showed that repeated freezing divided the serum into layers, of which the lowest was the most active in destroying bacteria, and that this power of the serum is destroyed if it be diluted with distilled water, or if it be dialyzed against it. After Buchner, the most important work has been done by Ogata and Iasuhara, and Behring and Kitasato, in showing the great influence of the fluid portion of the animal tissues in the acquisition of immunity. According to the work of these authors, immunity is due to the action of albuminoid substances, called by Hankin defensive proteids, which have the power of destroying pathogenic bacteria, of attenuating them, and of destroying their toxic products.

It is necessary that one should have a clear idea in regard to these defensive proteids, if one is to understand what extreme importance is to be attached to their discovery, and to the prosecution of researches upon them.

First, in regard to germicidal proteids. Certain animals have in their blood, and the other fluids of the body, substances endowed with a very considerable germicidal power, and an example that has been better studied than some others is found in the blood of the white rat. These animals are refractory to inoculation with anthrax, and the reason for this immunity to so virulent a disease has been found by Behring to exist in the fact that the animal's blood-serum destroys the bacteria. By comparative tests it was shown that two and one-half centimetres of rat serum possessed the same germicidal action as would the same quantity of corrosive sublimate in the strength of one to one thousand, or of carbolic acid (one to fifty). To appreciate this fact it is necessary to consider another quality of chemical germicides, viz., the toxic action of these materials upon the animal. Thus, for example, it appears that both the sublimate and the carbolic acid will kill the animal in a dose five to seven times smaller than is necessary to secure their germicidal action, and that they cannot therefore be thought of for internal antiseptics, while the germicidal proteids are present in quantity sufficient for the perfect accomplishment of such germicidal action in the serum of the perfectly healthy white rat. This is the most striking and valuable property of these defensive proteids, viz., that they are the least toxic of all germicides known, and this leads up to the more important fact that it seems possible to employ them in active measures for the treatment and cure of infectious disease.

Many points, of course, still remain to be cleared up, as, for instance, such an apparent contradiction as that the serum germicidal power does not, in all cases, correspond with the natural immunity of the animal furnishing the serum; but thus far investigation has only served to show that these apparent discrepancies can be easily explained.

The second class of these proteids is made up of the attenuating varieties, the existence of which was first suggested by the fact that the bacteria of symptomatic anthrax were attenuated in virulence when injected into animals refractory to the disease, and yet at the same time their vitality was not interfered with. It is to the work of Ogata and Iasuhara that we owe the first experimental determination that this attenuating property resided in the serum of the animals experimented upon, and not elsewhere.

Such an attenuating action upon bacteria would explain very naturally the immunity of the animal in whose blood it was found, and the authors, by further experiments, showed that this property continued to exist in the serum after its removal from the body of the animal in which it was found, and could be made to serve as a retarding influence, and even as a curative agent, in animals inoculated with true anthrax. The existence of these attenuating proteids has been confirmed by other observers in the case of anthrax and in other diseases, and the establishment of the fact would be exceedingly important if this were all; but further research has shown the existence of a third class of these proteids.

We know now that there are not only germicidal and attenuating, but also *antitoxic proteids*, and their discovery is the most important of all. The former classes act directly upon the bacteria themselves, either by actually destroying them, or by so limiting their development in the animal's body that their growth becomes a matter of slight moment as affecting the health of the individual attacked.

The first announcement of results in this direction was made by Behring and Kitasato in 1890 (see the quotations above). They had found that the blood of rabbits protected against tetanus had the power of destroying the toxic alkaloid of tetanus (tetanin) in the lifetime of the animal attacked. They also found that it was not only possible to protect animals against an inoculation of the tetanus bacilli, but also to cure it after this inoculation had taken place, and even after the appearance of the symptoms of the disease.

The importance of such results, especially as they have been repeatedly verified by independent observers, can hardly be over-estimated. Almost in the same week with the announcement of the discovery made by Behring and Kitasato with reference to tetanus came those of Fraenkel and Brieger in regard to diphtheria; and it is with regard to these latter, of course, that we are especially interested. So far as tetanus is concerned, if later reports can be trusted, the method of cure has been successfully applied in a number of cases which, as we have every reason to believe, would have terminated fatally, as such cases almost invariably do. Results similar to these have been obtained in animals in the case of some of the suppurative bacteria, in anthrax and in erysipelas, and the variety and extent to which experiments must go in the elucidation of the points brought up by these new facts, are almost unlimited.

As will be readily seen, we have at last caught sight of materials effective for the destruction of the bacteria, or their toxic products—materials that at the same time will leave the animal tissues unharmed after their application. Hitherto we have been able to employ for such a purpose only materials that were in themselves destructive to the vital organism, and the remedy, when effectively employed, has been worse than the disease.

The Toxalbumins of the Diphtheria Bacillus.—The toxalbumins of the diphtheria bacillus are at present attracting so much attention that the following account of the work of Wassermann and Proskauer (*Deut. Med. Woch.*, April 23, 1891) in extracting them can scarcely fail to be of interest.

Employing methods very similar to those of Brieger and Fraenkel (detailed in the *Berliner klin. Woch.*, 1890, Nos. 11 and 12) they attempted to follow out the same line of investigation. For their observations they used

a culture of the bacillus of diphtheria in bouillon which was about three weeks old and whose activity against animals was proved by experiments. This bouillon culture was made in the usual meat-water-peptone bouillon, with one per cent. of peptone and one-half per cent. of common salt. Its virulence was tested upon animals. One-tenth of a cubic centimetre of it injected into the animal was found to kill guinea-pigs after from twenty-four to thirty-six hours. Of such a bouillon culture three litres were made bacteria-free by passing through Kitasato's filter. That the filtrate was free from bacteria was proved by a double method of testing it: by cultivation upon nutrient agar, and further by leaving it in the brooding-oven for from twenty-four to forty-eight hours. After it was shown to be sterile by these tests, it was reduced to one-third of its bulk in a vacuum exsiccator at a temperature of from 27° to 30° C., having been made strongly acid with acetic acid. Absolute alcohol was added in the proportion of eight to ten times its mass, and the resulting precipitate was filtered after standing for twenty-four hours. This precipitate was then dissolved in water and further treated, and the operation was repeated as often as was found necessary to render the watery solution perfectly clear. Then it was three times dialyzed for twenty-four hours, and after dialyzing it was further treated with alcohol, and the precipitate collected and dried *in vacuo* at 37° C.

The observation was made that after leaving the precipitate in solution for one or two days in alcohol it became manifestly smaller in bulk. If this were then filtered and the filtrate again treated with absolute alcohol, *another precipitate* was obtained, differing markedly from the first.

It thus appeared clear that a part of the precipitate was more soluble in alcohol than the other, and as the alcohol was made more dilute it passed again into solution. This observation coincided with that of Brieger and Fraenkel, who, in their solutions, were able to isolate two bodies possessed of different solubility in dilute and absolute alcohol.

It was further observed that both bodies dialyzed very slowly; that they both gave the albumin reaction, and that only one of them was possessed of pathogenic properties. After a large mass of this bacteria-free material had been obtained, it was treated *in vacuo* at between 27° and 30° C., and was reduced to a tenth of its volume. Then at a low temperature it was dialyzed against distilled water for twenty-four hours three times, in order to get rid of the peptone and globuline. The authors were able to observe in neither of these—the peptone or the globuline—any pathogenic or poisonous properties. The peptone was obtained in fair quantity, but the globuline in very small quantity. The fluid obtained in the dialyzer was filtered clear, and only when it was obtained clear were the next procedures carried on. Seven times its volume of from sixty to seventy per cent. alcohol was added to the clear filtrate (freed of globuline and of the greater part of the peptone), the alcohol having previously been made acid with a drop or two of acetic acid. The precipitate thus obtained remained in alcohol for twenty-four hours, after having been allowed to settle for some time. It was then filtered and the dilute alcohol—the filtrate—was again treated with alcohol, and as often as a new precipitate was obtained it was again collected on the filter. Both substances were treated with water and the solution thus obtained again precipitated and treated as before. In order to free it as far as possible from peptone, it was treated with twice its bulk of a saturated solution of sulphate of ammonia, and the precipitate resulting from this, which contained the albumoses, was again brought into solution with distilled water, then passed through the dialyzer in flowing water until the reaction with sulphuric acid and ammonia disappeared, and finally was brought into solution with as small a quantity of absolute alcohol as was possible. This procedure—dissolving in water and precipitating with alcohol—was repeated until the solution became as perfectly clear as water. When this point was reached the precipitate was collected from the filter and dried *in vacuo* at 37° C.

In this way were obtained from cultures of diphtheria two albuminoid substances which resembled very closely those of Brieger and Fraenkel. The body precipitated by dilute alcohol was a finely granular white powder, while that thrown down by absolute alcohol, after drying, appeared in the form of a yellowish-brown, crystalline body. Both dissolved very easily in water, and these solutions gave simply albuminoid reactions. These bodies were broken up by concentrated mineral acids, by strong metallic salts, and by acetic acid, but this was not effected by nitric acid, by bisulphate of soda, or by warming the solution. They also gave the typical color reaction for albuminoid bodies.

The elementary analysis of the white toxic body gave the following from its ash: Carbon, 44.82 per cent.; hydrogen, 6.91 per cent.; nitrogen, 16.18 per cent.; sulphur, 1.69 per cent.; oxygen, 30.40 per cent.

The same analysis obtained by Brieger and Fraenkel, for their material gave: Carbon, 45.35 per cent.; hydrogen, 7.13 per cent.; nitrogen, 16.33 per cent.; sulphur, 1.39 per cent.; oxygen, 29.81 per cent.

The difference between the two analyses can be easily accounted for by the difficulty of the task. It was found that only the pure white, easily precipitated material had any toxic effect upon animals, while the other, even in considerable mass, could be injected without any unfortunate results following its use.

Investigations of this kind, as well as those of Behring, give promise of future results that are almost boundless in their extent and importance. The pity of it all lies in the fact that we in this country must stand idly by, powerless to help in pushing on these investigations, because of the lack of support for them in the way of money and institutions endowed for such researches.

Harold C. Ernst.

DIPHTHERIA IN CHILDREN. Membranous formation occurs very rarely in children under one year, but it has been seen even in the newly born. Most cases occur between the ages of three and fifteen. The clinical diagnosis of diphtheria covers at least two diseases, caused, one by the Klebs-Loeffler bacillus, the other by a streptococcus, and according as the disease is the one or the other, the symptoms vary somewhat, and the prognosis differs widely. A mixed infection is, however, not infrequent. A bacteriological examination is the only means of distinguishing positively between the two.

True Diphtheria, Due to the Klebs-Loeffler Bacillus.—The patient presents local and constitutional symptoms, the former the result of the position and extent of the membrane, the latter the result of the absorbed products of the bacilli.

Local Symptoms.—The membrane may be visible, or, by reason of its location, invisible. When visible it may be a mere point on one tonsil, or it may cover both tonsils, the soft palate, uvula, pillars of the fauces, and pharynx. It may extend up through the naso-pharynx and the nose, involve the conjunctivæ, and even appear in the ears. It may also cover the inner surfaces of the cheeks and extend out upon the skin. On the other hand, it may be confined to an area out of sight, or it may extend into the larynx, down the trachea and small bronchi, and rarely down the œsophagus. The membrane may be thin, transparent, and like a white veil, or thick and opaque; and in the latter case it may be yellow, green, gray, or black. It may be firm and closely adherent when young, or loose, shreddy, and soft when old. It may disappear in less than two days, and may last three or four weeks. Usually, however, the membrane begins to separate on the fourth or fifth day, and in about ten days the throat clears and convalescence begins. When the disease affects the neighborhood of the larynx there may be dyspnœa, due to a functional paralysis of the vocal cords, or to actual obstruction by membrane. With the dyspnœa come an altered voice, perhaps aphonia, and a cough. If the obstruction is considerable, cyanosis and retraction of the intercostal, supra-sternal, and supra-clavicular spaces are evident. If the naso-pharynx or nose

is affected, there may be complete occlusion of either or both nostrils, epistaxis, and there is regularly an acrid, watery, or purulent discharge.

Constitutional Symptoms.—The constitutional symptoms may be almost entirely absent, and on the other hand, when the local signs are slight, prostration may yet be extreme. Initial chilliness, aching of body or limbs, anorexia, and some soreness of the throat, are customary. The temperature may be very slightly raised, normal, or subnormal. Albuminuria, which is present in about half the cases, may begin the first day, and there may rarely follow a severe nephritis with uræmia. Rapid, feeble pulse, emaciation, prostration, and intense pallor are characteristic of toxæmia from absorption of ptomaïnes, and this toxæmia in a mild form may persist for weeks after the disappearance of the membrane. It is then probably due to continued slow absorption of ptomaïnes stored near the original site of infection. Paralysis, the result of a multiple neuritis, is frequent, and may come at any time from three days to six weeks after the beginning of the disease, but occurs oftenest in the second or third week of convalescence. The parts affected are primarily the soft palate and the muscles of accommodation, but all the muscles, even those of respiration and the sphincters, may be involved. The knee-jerk may be absent from the first day of the disease. There may be some slight cervical glandular enlargement, but in such a case there are usually streptococci present with the bacilli. With the mixed infection, too, there may be a broncho-pneumonia, which, like the persistent toxæmia, may kill the patient after the active disease is over. Various skin rashes may appear at the onset or later, and temporarily confuse the diagnosis.

Prognosis.—True diphtheria is extremely fatal in children under two years; children under one year almost never recover. Death is usually the result of one of the following causes: (1) Laryngeal stenosis; (2) septic infection; (3) broncho-pneumonia; (4) diphtheritic paralysis; (5) uræmia. Factors which increase the gravity of the prognosis, in any case, are marked prostration, great extent, thickness, and rapid spread of the membrane, long persistence of the membrane, its presence in the larynx, much albumin in the urine, the supervention of broncho-pneumonia, complications with other diseases, and persistent vomiting, especially if nourishment is taken poorly. On the other hand, a thin, slowly spreading membrane is favorable, as is one confined to a small area. Membrane which spreads to the naso-pharynx is unfavorable, but if it is confined to the nose, recovery is to be expected. From paralysis recovery is usual, after a period varying from one week to six months.

Pseudo-diphtheria, the Result of Infection by Streptococci.—As in the true diphtheria, the symptoms are local, due to the membrane, and constitutional, due to the penetration into the tissues of the cocci and to the entrance into the circulation of their poisonous products.

Local Symptoms.—The membrane cannot be positively distinguished in site or appearance from that of true diphtheria, and the symptoms due to its presence are the same.

Constitutional Symptoms.—There is frequently considerable temperature—103° to 104° F.—without any corresponding prostration. Glandular swelling is usually quite marked. Frequently, too, a broncho-pneumonia develops, sometimes late, but usually in the first week; if this does not happen, however, convalescence is extremely rapid.

Prognosis.—The prognosis is much better than in the true form, the mortality being about three per cent. in uncomplicated cases of the pseudo-diphtheria, as compared with a mortality of about thirty per cent. in the real diphtheria. Factors which are unfavorable are: (1) Complication with other infectious disease; (2) broncho-pneumonia; and (3) laryngeal stenosis. In the last case, if intubation or tracheotomy be performed, the prognosis for recovery is good.

Treatment.—Prophylactic treatment should be advised for children, especially those in institutions. Such consists in reduction of hypertrophied tonsils, care of the teeth, and the use of antiseptic gargles. All, old or young, exposed to cases showing membrane in the throat, should use frequently some antiseptic gargle.

Isolation of the patient should be absolute in the true form, but need not be so rigid in the pseudo-diphtheria. In the latter, however, contact with children should be carefully avoided. It is as yet uncertain whether bacilli are, or are not, found in the throat after the membrane has disappeared. It is wise, therefore, to continue such isolation for a week after the membrane has gone, and to continue antiseptic gargles during that time.

Local Treatment.—Any injury to the mucous membrane allows the membrane to spread; therefore all rough applications and swabbing are to be avoided.

Sprays are not notably efficient; but of the beneficial effect of steam in laryngeal cases, before and after operation, there is no doubt. The steam from kettle, steam-pipe, or other source, should be delivered close to the face of the patient.

Fumigation by calomel is certainly successful in coating the larynx, trachea, and larger bronchi with the powder, and with this substance there is, in addition to the local effect, a constitutional action. The method is to construct a close tent of sheets over the bed, and then to volatilize within the tent, on a metal plate, over an alcohol or oil flame, twenty grains of calomel. The tent should be kept closed except for frequent inspection of the patient, till the odor of the calomel has nearly disappeared, *i.e.*, usually about half an hour. This fumigation should be repeated at hourly intervals till the constitutional effect is reached, and this means hourly fumigations for at least twenty-four, and sometimes for forty-eight hours.

Irrigation with an antiseptic solution is probably the most efficient local treatment. The solution can be directed by an ounce-syringe fitted with a short, soft rubber cap over the point, so as not to hurt the tissues touched, and the solution should be forced up one nostril and made to return by the mouth or other nostril. To do this it may be necessary to push the piston home with considerable force, but the nozzle should not plug the nostril so tightly that, if the obstruction is considerable, fluid may not pass back out around the nozzle. Perhaps the best solution for this purpose is corrosive sublimate in strength from $\frac{1}{4000}$ to $\frac{1}{1000}$. Some will be swallowed accidentally, but not enough to be injurious. The mouth is to be irrigated in every case, the nose when there is any discharge. The irrigation should be made every half-hour or hour. It is very regularly the rule that after the irrigations are begun the membrane stops spreading.

Constitutional Treatment.—The three drugs most to be relied on are alcohol, mercury, and iron.

Alcohol is best given in the form of brandy or whiskey, and the dose should be at one-hour or at most two-hour intervals. Its use should be begun early, and in grave cases pushed to the utmost short of narcotism. Nearly every case at all ill, will take three ounces in twenty-four hours, and a child, six years old, may need ten or twelve ounces in the same time.

Mercury is given internally in the form of the bichloride, one-sixtieth of a grain every hour for children under five years, and one-fortieth of a grain for those over five.

Iron, as the tincture of the chloride, in glycerine, to prolong the local effect, should be given frequently in small doses, two to five minims every half-hour, for a child six years old.

Food, in easily digestible form, should be given in as large quantities and as frequently as the patient will take and digest it.

Treatment of Laryngeal Stenosis.—In the beginning, steam inhalations and emesis are advisable. If operation becomes necessary, it is to be remembered that mortality is less in early operations. If the consent of the parents is obtained for either intubation or tracheotomy, the choice depends mainly on: 1, The experience of the physician; 2, the age of the patient. A physician without

considerable practice will usually do better with tracheotomy, and it is wise to be prepared always, at an intubation, to do an immediate tracheotomy if the first operation fails. Intubation is to be preferred if the patient is less than two years old. *John H. Huddleston.*

DIURETICS. Two diuretics of striking power have lately come into use. One of them, calomel, was formerly much used in combination with squill and digitalis; the other, sodio-theobromine salicylate, or diuretin, was introduced in 1890.

Calomel.—The diuretic power of calomel was discovered by Jendrassik[1] and announced by him in 1886. It had, however, been observed long before that calomel, in cases of dropsy, sometimes caused very profuse diuresis; but this was forgotten, and the writers on therapeutics in the last two decades either entirely ignored the use of calomel as a diuretic, or recommended it only as an adjuvant to squill and digitalis.

Jendrassik accidentally, in a case of dropsy, with syphilis, found that calomel acted as a powerful diuretic. He then tried it in other cases of dropsy. In cardiac dropsy its use was almost uniformly followed by profuse diuresis, but in renal dropsy, in ascites, and in pleuritic effusion, no very decided effect resulted, and in most cases none at all. Jendrassik's success led others to try calomel. On the whole, their reports show that in cardiac dropsy calomel produces marked diuresis, but acts feebly or fails to act in other forms, but especially in renal dropsy.

All observers found that the polyuria does not begin on the first day of administration, but usually on the second, the third, the fourth, or the fifth day. The quantity of urine then augments very rapidly, is most profuse on the second day, and subsequently slowly diminishes. As a rule, the polyuria continues until the symptoms of dropsy have completely disappeared. In cases of extensive dropsy the maximum quantity of urine voided in one day was twenty pints.

As the quantity of calomel necessary to produce such profuse diuresis is quite large, the ordinary effects of large doses supervene, unless prevented by prophylactic measures. Diarrhœa nearly always results. If not more than two or three stools occur daily, diuresis may still take place; but if the stools are very numerous no increase of the quantity of urine will result, doubtless because the calomel is expelled from the intestines before absorption can take place. To prevent such rapid discharge of the medicine, opium in small doses should be combined with it.

Some of the general symptoms of acute mercurialism usually become manifest—a disagreeable metallic taste, some soreness of the gums, increased secretion of saliva, and offensiveness of the breath. Some patients, however, have taken calomel in moderate doses for ten or twelve days without any of these effects. In most cases, if the calomel be long continued, the effects on the mouth become very severe, and some cases have been reported in which extensive ulceration and even gangrene resulted. Hence no more calomel should be employed than is necessary to cause decided diuresis. To prevent the effects upon the mouth, prophylactics should be used from the beginning of the treatment. Generally chlorate of potassium is preferred, the mouth being rinsed every two or three hours with a three or four per cent. solution of the salt. Jendrassik supposes that an acid reaction in the mouth, especially in the vicinity of decaying teeth, greatly favors stomatitis, and he has used with success a three or four per cent. solution of carbonate of sodium. Tincture of myrrh, tincture of krameria, and permanganate of potassium have also been used as preventives. If, notwithstanding the employment of these means, stomatitis should take place, the use of calomel must be discontinued. But it is not likely to occur, or only very mildly, if the calomel be given in the cautious manner lately recommended by Jendrassik.[2]

Calomel as a diuretic is indicated in cardiac dropsy when other appropriate means, such as digitalis, strophanthus, caffeine, diuretin, etc., fail to give relief. The presence of albumin in the urine does not interfere with the action of calomel, and generally the urine, if it contain albumin, will become normal after the subsidence of the dropsy. It should be recollected that the mere removal of the dropsy does not restore compensation in cases of cardiac insufficiency, and that, after the diuretic has proved successful, it will be necessary to administer remedies to improve the heart's action. Should these not succeed and the dropsy return, calomel should again be used, and, if necessary, it may be employed as often as the dropsy becomes extensive. Its employment at intervals of some weeks becomes necessary in some cases of heart disease in which the rupture of compensation cannot be rectified. If the calomel be carefully used no harm will result, and the patient may be made comfortable and life be prolonged for some years. Jendrassik states that he treated a patient whose life had been prolonged for five years; each year it was necessary to give calomel from fifteen to twenty times to remove the dropsical symptoms. In the intervening periods the patient was able to lead a tolerably active life. Another patient that had marked insufficiency of the heart had been treated seven times since 1886. On each occasion he came to the hospital with grave symptoms—enormous anasarca and ascites, with severe dyspnœa and sleeplessness. His urine always contained albumin. Once the ascites was so extreme that, to save life, it was necessary to tap the abdomen. In this case the calomel always acted well and enabled the patient to return to active life. Jordan has recorded a case in which twenty-three successful trials with calomel were made, and during the treatment the patient took, without perceptible injury, 107.5 grammes (nearly 3¾ ounces) of calomel.

The dose of calomel in most of the reported clinical experiments was three grains, given from three to five times daily for several days, usually together with one-sixth grain of opium to prevent catharsis. Lately Jendrassik has stated, after further experience, that one and a half grain is the best single dose, and that this should be given eight or ten times within a day. After the administration for one day the polyuria, he says, is just as profuse on the third or fourth day as if the medicine had been given on the intermediate days, and that it is certainly erroneous to persist in the administration of calomel after the urine has begun to increase in quantity.

Jendrassik holds that the diuretic effect is caused by increased resorption of the dropsical fluid by the blood. In the cases in which calomel acted very decidedly no changes in the circulation took place that would account for the polyuria; hence it does not act like digitalis and some other medicines that increase blood-pressure. In experiments Jendrassik found that a very dilute solution of chloride of sodium diffused into a solution of albuminate of oxide of mercury, placed in a suitable dialyser, in much greater quantity in a given time than into a simple solution of albumin of the same strength. As calomel after absorption doubtless circulates in the blood as an albuminate, Jendrassik supposes that it causes the dropsical fluid to pass by endosmosis into the inspissated blood in greatly increased quantity, thus rendering the blood more watery. The excess of water in the blood, as soon as it reaches the kidneys, is rapidly excreted.

Experiments made by Benczur and Csatary[3] support this view. They determined the quantity of hæmoglobin in the blood of patients for several days before and during the administration of diuretics. From the quantity of hæmoglobin found they calculated the degree of concentration of the blood. In a case of dropsy they gave forty drops of tincture of strophanthus for three days. The quantity of urine voided in the three days was, respectively, 900, 1,900, and 3,200 c.c. On these days 100 c.c. of blood contained 7.851, 8.659, and 8.730 grammes of hæmoglobin. This shows, say Benczur and Csatary, that the diuresis produced by strophanthus is associated with a simultaneous inspissation of the blood. In a case of severe cardiac dropsy they gave 0.2 of calomel six times daily for two days. The quantity of urine in these two days, and in the following four

days, was as follows: 950, 1,000, 3,900, 4,500, 2,400, and 1,000 c.c. The quantity of hæmoglobin contained in 100 c.c. of blood in the same days was as follows: 7.19, 5.32, 7.93, 7.85, 9.31, and 8.32. These figures seem to show that when calomel produces free diuresis the blood at first becomes hydræmic, and that inspissation takes place only during the progress of the polyuria. Hence Benczur and Csatary contend that calomel increases resorption, thus rendering the blood very watery, and that the kidneys simply remove the excess of water in the blood.

Stintzing and some others hold that calomel acts directly upon the kidneys, because they observed an increase of the urine of some patients not affected with dropsy. Some clinicians concluded that it acts upon the epithelium of the kidneys because it manifests no diuretic action in the dropsy of chronic parenchymatous nephritis.

Recently Cohnstein[4] experimented upon healthy rabbits to determine the mode of action of calomel, without, however, succeeding in solving the question. He used a solution of calomel in hypophosphite of sodium. When this was injected into the subcutaneous tissue or into the jugular vein a decided increase of diuresis resulted, showing conclusively that calomel acts as a diuretic in healthy rabbits. When before the injection he had placed the animals under the influence of chloral in order to depress the vaso-motor centre, no increase of the urine took place; so, also, no augmentation of the urine resulted from one of the kidneys when, before the injection, its nerves had been severed. But in both series of experiments, after calomel had failed, the administration of caffeine decidedly increased the quantity of urine. From these experiments Cohnstein concluded that some change in the circulation is a necessary condition of the diuresis, and that calomel does not act by stimulating the epithelium of the kidneys. In some of his experiments Cohnstein determined the blood-pressure after small doses of calomel, and found that simultaneously with the increase of diuresis an augmentation of arterial pressure took place, but this was slight and evanescent, and could not have caused the heightened secretion of urine.

Diuretin.—The term diuretin is applied to a preparation of theobromine, as a convenient substitute for the unwieldy chemical name sodio-theobromine salicylate. As this chemical name indicates, diuretin is a double compound of sodium theobromine, $C_7H_7NaN_4O_2$, and sodium salicylate, $C_6H_4(OH)COONa$.

Diuretin is a white, odorless powder, having a bitter taste. It dissolves in less than its weight of water when warmed, and remains in solution on cooling. It is a very unstable compound, and when exposed to the air gradually decomposes, the theobromine separating from the sodium. On account of this instability aqueous solutions undergo change in a few days, and, when administered soon after meals, become decomposed by the acid of the gastric juice.

W. von Schroeder[5] discovered, in experiments upon rabbits, that theobromine greatly increases the secretion of urine by acting directly upon the epithelium of the kidneys, and that it has no action on the vaso-motor centre, in this respect differing from caffeine. As the human kidneys are affected in the same manner as the kidneys of the rabbit by caffeine, he supposed that theobromine would in man also produce a very decided diuretic effect, and, on account of its slight action on the nerve-centres, in many cases be preferable to caffeine.

Chr. Gram,[6] at the suggestion of von Schroeder, tried free theobromine in cases of dropsy. It acted effectively as a diuretic, but frequently caused vomiting, and was inconstant in its diuretic action, owing to its slow and uncertain absorption. After unsuccessful trials of various preparations of theobromine, he finally found one that is easily absorbed, namely, diuretin.

Gram administered diuretin in cases of dropsy in which other diuretics, digitalis and strophanthus, had failed. He states that he purposely selected cases in which as a rule we are utterly helpless. Diuretin always increased the quantity of urine, except in those cases in which the renal epithelium was so degenerated that no action could be expected. In some cases a relative cure resulted, or at least decided improvement, a result that may be called a good one when it is considered that in severe organic heart disease and in chronic nephritis only a relative cure can be attained. Gram says that the therapeutic results of his experiments were not very remarkable, but yet, as the patients were in such a desolate state that other diuretics (cardiac tonics) could not act efficiently, these results appear to have been very favorable. The usual dose of diuretin was 1.0 (fifteen grains), which was given five or six times daily. No changes in the circulation took place, and hence the increase in diuresis resulted from a direct action upon the kidneys. The remedy never produced disagreeable incidental effects, and only once, in a very cachectic patient, did it cause slight giddiness.

A. Hoffmann[7] tried diuretin in numerous cases. In four cases of cardiac dropsy he employed it on fourteen different occasions, and always obtained good results. Usually diuretin was not given until digitalis had failed to act. The polyuria began on the first day of administration, augmented gradually, and reached the maximum in from two to six days. It rapidly diminished when the diuretin was withdrawn, or when the dropsy had subsided. Sometimes the diuretic action was delayed for several days, perhaps on account of slow absorption. The quantity of urine voided depended upon the extent of the dropsy; when this was very decided the quantity at the maximum amounted to five or six litres a day.

Hoffmann agrees with von Schroeder that diuretin acts directly upon the kidneys, but he supposes that it also influences the heart. He observed that the pulse often became regular, stronger, and slower; that dyspnœa was relieved before the disappearance of the dropsy; and that quiet sleep ensued without the use of hypnotics. No incidental effects took place, except some vomiting in a few cases; but this soon ceased. In several cases a light, painless diarrhœa occurred, but stopped although the medicine was continued. Excitement, such as sometimes occurs from caffeine, was never observed. Hoffmann concluded that diuretin is a powerful diuretic in general dropsy, but has little effect upon inflammatory exudations, such as that of pleuritis, and still less upon ascites from portal obstruction.

Dr. Koritschoner[8] employed diuretin in thirty-eight cases of severe dropsy of cardiac, renal, and hepatic origin. In twenty-three cases the effect was better than from other diuretics, and in eight of them very remarkable, the quantity of urine having increased to ten or twelve litres. In ten cases the effect was moderate, but was not excelled or equalled by any other diuretic. Only in one case was complete failure observed. On the average the action of diuretin was best in cardiac dropsy, next in portal obstruction, and least in nephritis. But this pertains only to the absolute action; relatively to other diuretics the action in chronic Bright's disease was very satisfactory. Koritschoner supposes that diuretin acts directly upon the kidneys, as he observed no influence on the heart. He knows of no contraindications to its use. Even when employed for a long time it proved innocuous. He began with 4.0 (one drachm) daily, and increased by one gramme daily until the quantity of urine, compared with the ingested fluid and the subsidence of the dropsy, gave a satisfactory result. In sixty per cent. of the cases 5.0 daily sufficed; in thirty per cent., 6.0 daily; and in ten per cent., larger doses up to 10.0. The medicine was given in solution, made with hot water, in tablespoonful doses, at intervals of one or two hours, beginning three hours after the principal meal.

R. Demme[9] tried diuretin with good results in dropsy occurring in children. The dropsy of scarlatinous nephritis seemed, after the first stage of the nephritis had passed, to be removed more rapidly by diuretin than by all other diuretics. Anasarca and effusions in the serous cavities resulting from mitral insufficiency subsided, after the valvular disease had been compensated by digitalis, very speedily when diuretin was given. The dose for children from two to five years old was 0.5 to 1.5, and from six to ten years old, 1.5 to 3.0 daily. Diuretin

should not be given to infants under one year, as in them it easily causes irritatiou of the stomach and intestines.

Von Schroeder states[10] that some preparations of diuretin found in commerce contain only from thirty to thirty-eight per cent. of theobromine, as found in the analyses made by Vulpius. Knoll's preparation was found to contain forty-eight per cent., and hence should be preferred by the practitioner. Von Schroeder recommends the following formula :

℞. Diuretini (Knoll)..... 5.0–7.0
Aq. destill..... 90.0
Aq. menth. pip..... 100.0
Syr. simpl..... 10.0
M. S.: One tablespoonful every two or three hours.

DIURETIN. This name was given by Dr. Christian Gram, of Copenhagen, to the salicylate of theobromine and sodium which he introduced as a substitute for caffeine. Professor Schroeder, of Strasbourg, had experimented with the alkaloid theobromine, and had reported upon its important diuretic properties at the meeting of the German Medical Congress in 1889. He had found that caffeine in small doses often failed to produce diuresis, and where the vascular tension of the kidneys was increased, the flow of urine sometimes diminished on account of the increased blood-pressure produced by the caffeine. Large doses overcame this effect, but they were liable to cause nervousness and insomnia, and other distressing symptoms. Theobromine he found to be an equally efficient diuretic without producing any nervous symptoms or affecting the blood-pressure ; chemically, it differed from caffeine by containing one equivalent less of methyl, it being the dimethyl-xanthine and caffeine the trimethyl-xanthine. The difficulty in using the alkaloid was its insolubility, it requiring 1,600 parts of water for its solution. At his suggestion Dr. Gram instituted a series of experiments, and succeeded in producing a soluble salt by combining it with salicylate of sodium. It is said to be prepared by dissolving one molecule (180) of theobromine in one molecule (40) of soda hydrate, and adding to the solution one molecule (160) of salicylate of sodium ; when evaporated to dryness it should yield 362 parts of the double salt, which theoretically contains 49.7 per cent. of theobromine and 38.1 per cent. of salicylic acid. It is a white powder with a slightly bitter and disagreeable taste, very soluble ; by the aid of heat it dissolves in less than half its weight of water, and no precipitation occurs upon cooling. Its solution is very unstable and rapidly decomposes. It burns without leaving any residue.

To estimate the amount of the alkaloid an aqueous solution is acidified, then made alkaline with ammonia, and the precipitated theobromine collected on a filter, washed, and dried. The amount of salicylic acid may be determined by treating the filtrate and washings with ether, separating the ethereal solution and evaporating.

Theobromine exerts its diuretic properties by its direct action on the secreting tissue of the kidneys. It acts promptly and energetically, and its effect is maintained for a day or two after the cessation of the drug. Its action is not cumulative. The solids as well as the fluid are increased ; there is no marked change in the blood-pressure, but the heart becomes slower, stronger, and less irregular. An improvement in the general condition of the patient is also experienced. It does not produce any excitement nor influence the nervous system unfavorably, nor does it derange the digestive organs. Reports of its prolonged use, however, show that it may be accompanied by diarrhœa and other signs of intestinal irritation. In all forms of dropsy due to renal disease its action is most efficient ; there is no irritant effect on the secreting cells, and no unfavorable results follow its use. It is of service in all dropsies accompanying heart-disease, but is said to be of greatest service where there is organic disease and failing compensation. Where digitalis and other cardiac tonics have been used without success, it will generally be found to succeed, by its action on the kidneys following that of the other forms of diuretics. A combination of digitalis and diuretin will form a very active diuretic mixture in dropsies where the blood-pressure requires to be raised. It has not been found of so much value where the dropsy arises from inflamed serous membranes, or where the liver is congested. The following are the conclusions of Dr. Dujardin-Beaumetz :

(1) When given in doses of fifteen grains it is a much stronger diuretic than caffeine ; (2) when there is considerable cardiac degeneration it should be used with some caution, especially when there is albuminuria ; (3) under its influence the cardiac contractions are scarcely affected ; (4) diuretin rapidly increases the quantity of urine passed, and the diuretic effect lasts twice or three times as long as that produced by caffeine ; (5) the activity does not wear off as the patient becomes accustomed to the drug ; (6) micturition is not rendered difficult or painful ; (7) diuretin has no action on the central nervous system.

The dose is from sixty to ninety grains daily. It has been found most active in fifteen-grain doses every two or three hours, in water with some aromatic essence to disguise its bitter taste. Care should be observed in selecting the remedy, on account of its instability. When exposed to the atmosphere it absorbs carbonic acid and separates the alkaloid, which is insoluble. The addition of acids or acid vegetable juice also decomposes the solution by throwing down the alkaloid. It has been found a safe remedy for children above one year of age, and has proved of marked benefit in scarlatinal nephritis. At the age of from two to five years the dose may be from eight to twenty-five grains in the day, and at the age of from six to twelve, from twenty-five to forty-five grains. The total amount for the day may be dissolved in four ounces of water with ten or twelve drops of brandy and a little sugar. It has been given for weeks without producing any ill effects or lessening its therapeutic action.

Beaumont Small.

DROITWICH. A watering-place chiefly noted for its brine baths, in Worcestershire, England.

Location.—Droitwich is pleasantly situated, about 3½ hours by rail from London. The town itself is dull. Its saline waters are among the most powerful known, and are now extensively used in the form of brine baths.

Analysis.—It is claimed that the Droitwich brine is stronger than any other European water of similar kind. It is fully ten times as rich in salts as the ocean, and has four times the density of the waters of the Dead Sea.

Indications.—Like the famous baths of Kreuznach, the Droitwich brine has been found useful in rheumatic gout, rheumatoid arthritis, muscular rheumatism, inflammatory exudations and periarticular thickenings, sciatica, neuralgia, nervous debility, pelvic cellulitis, uterine derangements, bronchitis, and various conditions of cachexia.

Accommodation.—A large swimming-bath has been recently added to the other conveniences of the town. The *Royal Brine Baths Hotel*, in connection with the above, has been placed under an experienced manager, and the comforts of home are now insured to invalids and others. It affords warm and comfortable winter quarters. The St. Andrew's Baths is the oldest establishment. *Edmund C. Wendt.*

DYSPEPSIA, NERVOUS. We will give the personal history of aggravated cases of the special form under consideration, which being of extreme gravity—the symptoms of some of them almost unparalleled—and the

treatment being successful, the chief features of the disease will be clearly indicated. One of these resulted in violent temporary insanity, another in threatened softening of the brain, a third in absolute loss of mental control, and others in melancholia, nervous depression, diplopia, etc.; in all of these cases the trouble being dependent solely upon malassimilation of food.

Case 1 is that of a young man whose time had been devoted chiefly to literary pursuits. In a personal sketch, which we give briefly in his own words, he states:

"My sufferings increased daily; I often felt that I was dying, while the terrors of death at such moments were intensified a hundred-fold. In the meantime a perceptible change was going on in my heart and mind, and friends united in censuring me for my eccentric conduct. They did not and could not understand that the morbid effects of the disease were slowly but surely gaining complete control over my thoughts and feelings, nor that when the functions of the nervous system are perverted the victim becomes, to a certain extent, an irresponsible agent and suffers complete transformation of character. I can truthfully say, from dreadful experience, that there are stages of this disease when the victim, like the drowning man grasping at a straw, will swallow anything in the shape of anodynes or stimulants for relief. Finding that alcoholic beverages mitigated my sufferings, I used them liberally at times; but knowing that such excesses must end in insanity or death, and not being able to use spirituous liquors at any time in moderation, I determined to discontinue them altogether. But without a stimulant I could not walk fifty yards without being seized with a nervous attack and dizziness. I could attend to no regular business, and had diminished in weight from 135 to 117 pounds."

He reported that he suffered severely from vertigo after any exertion, and had constant torpor of the bowels, with inability to sleep at night without recourse to stimulants or anodynes.

As the first step an immediate abstinence from tobacco, which he used to excess, was required; alcohol was allowed in moderation, and a hepatic stimulant and alterative, consisting of stillingia, belladonna, nux vomica, and physostigma, was prescribed. The improvement was marked and continuous; he now no longer suffers from vertigo, and sleeps without any anodyne.

Notwithstanding that some physicians inveigh against the use of lactopeptine, and deny to it the possession of any value whatever, we would say here that for such symptoms, namely, defective or complete loss of appetite, indigestion, and deficient activity of the digestive organs—whether in adults or children,—we find no remedy to compare with the following combination, to which we have recourse incessantly:

℞. Lactopeptine (Am. Pharmacal Co.)...	ʒ ij.
Subnitrate of bismuth.....	ʒ ij.
Comp. tinct. of gentian.....	ʒ j.
Simple syrup.....	ʒ j.
Ess. peppermint.....	ʒ ij.
Water..... to	ʒ iv.

M. Dessertspoonful in a wineglass of water before meals.

A half grain of strychnia added to the above, when indicated, increases its efficacy.

Case 2. *Nervous Dyspepsia Due to Poor Assimilation in Old Age.*—Mrs. B., a lady, aged eighty, had during her whole life been noted for ceaseless industry, physical activity, and mental soundness. She was a highly cultivated woman, of unusual good sense and excellent judgment; her digestion was always good, with no constipation, no malarial poisoning, nor any other disturbance of the system. She had during the war and of late years been subject to much harassment of mind—with, at times, more or less poor nutrition.

The first indication of the approaching attack was a tendency to garrulity, with a certain wilfulness of manner. She next exhibited extreme excitement; and, strange to relate, it was invariably most violent upon awakening in the morning just after sleeping soundly for hours, or at any time after sleeping; at such times she frequently screamed aloud. Her talk was incessant, coherent and incoherent, generally of a pleasant character; in her disordered fancies she would enjoy and describe visions of flowers, of bright parterres, decorated tapestries; she would repeat poetry and long reminiscences of her earlier life, all delivered in pleasant, but in highly figurative language. But at times she was beyond control, and may be said to have lost her mind, so entirely irresponsible were her actions.

Knowing the calming and soothing effect which sleep usually exerts upon violent inebriates with delirium and persons with various neurastheniæ, we were forced to the conclusion that she could not stand the depressing effects of sleep, which left her a prey to the uncontrollable excitement and loss of mental balance; all of these symptoms depending upon a lack of assimilative power, together with the absence of full and suitable nourishment. All hypnotics were therefore discontinued; she certainly did not require sedatives, for the compound "bromidia," and others freely used, had failed to give any relief.

A complete change in treatment was ordered, as follows: Fellows's syrup of the hypophosphites, C. P., *ter in die;* spiritus frumenti in substantial amounts, frequently repeated; beef extract, and other concentrated nourishment, with hot coffee upon first awakening. She yielded surprisingly well to these measures, which were kept up without any interruption until complete and entire control of herself was obtained.

The attacks have returned several times, at long intervals, and each time have yielded to the liberal use of stimulants, food, and the syrup of hypophosphites with strychnia; and the correctness of the diagnosis was absolutely proved by the almost immediate relief afforded by the treatment. She lived long afterward—dying at eighty-six,—having been, during these last years, in perfect health of mind and body.

Case 3.—A gentleman in middle age, after having passed through a great affliction, and being extremely imprudent in eating—indulging freely in nuts, raisins, and other indigestible substances in the intervals of his regular meals,—began to suffer from complete loss of appetite, and a train of nervous symptoms. He had attacks of dizziness to such a degree that he would have to lie prone upon the floor, or the ground, as the case might be; he could stand none of the ordinary draughts upon the reason or the intelligence, being unable to perform the daily duties of his calling; he could not write a letter, and feared to walk around the square upon which he lived. This culminated in such a low condition of the nervous system that he was twice prostrated, thought that he was about to die, and once asked a friend "if he did not know better than to look at him—that he could not stand it;" surpassing in this the weakest and most nervous female.

Complete recovery of appetite, health, and strength took place after a month's absence in a Northern city for rest and change of scene, with the prudent use of stimulants taken with the most nourishing food, but without any medicines whatever.

Case 4.—A gentleman, aged twenty-five, was so much afflicted with dyspepsia and ill-health, after prolonged confinement to books at school and college, that he repeatedly believed that he was dying, saw visions by night and day, was so timorous and fearful that he would not sit in the open seat of a vehicle without the grasp of some one's hand, neither would he leave a room for fear that he would die before his return.

These and other exhibitions of groundless apprehension and timidity were presented by a man who had previously, and has since, given striking instances of his manliness and courage. Dyspeptic symptoms so marked and violent, some of them approaching closely to those of hysteria, were also complicated with spermatorrhœa caused by ascarides.

He became much reduced in flesh and strength, but recovered perfectly after two operations by Lallemand's *porte-caustique*, efficiently applied, and some tonic remedies.

Case 5.—A patient, aged thirty-eight, after about a year of suffering from insomnia, constant constipation, and extreme nervousness, was thought by his friends to have softening of the brain and to be doomed to the lunatic asylum. It was at once apparent that his mind must be set at rest and some hope instilled into him. This was done by assuring him in the most confident manner that there was no serious organic disease present, that his nervous symptoms, being functional and neurotic, could be controlled, and that he would surely recover under judicious management.

An occasional mercurial laxative was given, his digestive organs were strengthened, and the tonic hepatic stimulant referred to in Case 1 was administered. As a result, his insomnia, general depression, and all fears of hereditary disease disappeared, and he is now in complete possession of health and strength.

Case 6.—The patient, a gentleman over fifty years of age, was strictly temperate in his habits; he had never any constitutional, malarial, or other disease, except at an early period, when he suffered from bronchitis, from which he recovered perfectly. He had once also experienced a severe attack of dyspepsia. Double vision, lasting each time from three to six weeks, occurred repeatedly—there being four separate attacks at intervals of months and years,—apparently from digestive derangements due to overtasking the organs by too free ingestion of some special article of food. There was no diarrhœa, colic, or other disturbance; no cerebral complication whatever, or any of the nervous symptoms characterizing the other cases reported here; the whole ill effect being a reflex influence upon the muscles of the eyes. Without employing the scientific minuteness of the specialist, we only say that there were no degenerative changes of the cerebro-spinal system, no disseminated spinal sclerosis, nor any diplopia such as is sometimes seen in locomotor ataxia. Furthermore, there was no inherent paralysis of the ocular muscles, but simply a reflex functional paresis by which the power of adjustment was lost. But when this occurs, be the cause what it may, then every object is duplicated. The man who walks upon the streets sees four lines of pavements stretching away in the distance instead of two, and the temporary loss of this habitual power of adjustment, which has been unconsciously possessed and exercised by him all his life, suffices to throw every visual object into confusion.

Each attack came on gradually, increasing in intensity, until each eye acted independently, every object beyond near reading distance, at which vision was normal, being seen separately, and one eye had often to be closed to relieve the inconvenience caused by the diplopia. In some of the attacks there was moderate strabismus; in one it was marked.

On the first appearance of the trouble, years ago, the reflex effects upon the eyes seemed to result from weakness of the entire system following an attack of bronchitis. The later attacks occurred in the midst of robust health, being directly connected with the stomach. As in two of these he had suffered from severe lumbago and rheumatism of the muscles of an arm lasting for weeks, it was thought that the condition might be dependent—as has been claimed by some authors—upon a gouty or rheumatic diathesis. It is susceptible of proof that all the attacks were not complicated by a rheumatic element.

The following prescription completely relieved every attack, when given in repeated doses and persevered with:

℞. Potassii iodid..... ʒ ij.
Tinct. cinchonæ comp..... ℥ j.
Aquæ.....ad ʒ iv.
M. S.: Dessertspoonful in wineglass of water, *t. i. d.*, between meals.

Fellows's syrup of the hypophosphites, one drachm, in water, before meals, was used simultaneously.

In two of the attacks when the rheumatism was prominent, the wine of colchicum and the tincture of guaiac were added to the above combination. Recovery was always gradual, and double vision for distant objects was always the last symptom to be relieved,—a picture on the wall being seen single, when a distant steeple or star was perceived as two objects far apart. By pressing on the left eye or slightly closing it the double vision could be prevented. Good appetite and general health, save in the attacks complicated by rheumatism, were maintained throughout, and, for the present, recovery is again complete.

In our own experience, which embraces the care of hospitals for a very long period, cases of this affection are of extreme rarity. We have personal knowledge of but three. Reference may be made to a paper by Dr. George T. Stevens, of New York, on "Sudden Attacks of Diplopia," in the *Annals of Ophthalmology and Otology*, Kansas City, 1892.

Such examples, which are met, doubtless, by every physician, show what a powerful disturbing influence dyspepsia can exert upon the mind and body—producing bodily weakness and depression of the general powers; lessening the energy, and even the inclination and the capacity to will and to act; specially giving rise to unmanly fears, indecision, causeless scruples, and apprehensions of impending death; and in many cases dizziness is a marked symptom.

We believe that in the impaired condition caused by malassimilation, defective quantity and quality, and irregularity in the taking of food, and consequent anæmia, by which the blood becomes impaired and the nourishment and the integrity of the nerves and the brain fail to be maintained, will be found the true pathology of cases such as these, which give rise to so much loss of time, painful anxiety, and suffering to the patient and to his friends. The recoveries under judicious management, change of air and scene, good nourishment, moderate use of stimulants—if they can be tolerated—strychnia, tonics, etc., support the correctness of this view.

It will be noticed that the above cases, marked by nervous disturbance, mental excitement or depression, do not include dyspepsias of reflex, or cardiac, or ovarian origin, referred to by Fothergill and others; nor is there any special implication of the liver or renal organs, no gastric catarrh, pyrosis, biliousness, vomiting of bile, or morbid deposits in excess in the urine, such as urates, phosphates, etc.—which morbid conditions are found so commonly in other types of dyspepsia.

We are induced to add a brief notice of another and very common form of dyspepsia, which is in striking contrast with that described above, in cause, nature, symptoms, and treatment. This is the gastro-intestinal type, characterized by acidity, water-brash, fermentation, distention, pain, etc., and which requires a distinct management with drugs quite different from those used in cases where there is simply malassimilation of food followed by marked nervous symptoms.

We are indebted to a leading article in the Boston *Medical and Surgical Journal*, for March 17, 1892, for suggestions as regards the management of such cases as follows:

"As this form of dyspepsia (intestinal dyspepsia) is generally predominantly a dyspepsia of starches, there is a leading indication to abstain from amylaceous and saccharine articles of diet. There should be a maximum of albuminoids—meat, eggs, fish—and a minimum of carbohydrates and fats. Brilliant results have been attained by a diet of raw meat—six to ten ounces of lean beef or mutton reduced to a pulp and cooked but slightly, if at all; to be eaten, well-seasoned, with a little bread, but without vegetables. Three slices of underdone roast meat, fresh broiled fish, raw oysters and other shell-fish, soft boiled eggs, boiled ham, together with sour-crout, smoked herring, a little stale cheese, etc., have been recommended, the latter articles being particularly unlikely to undergo putrefactive decomposition.

"Chronic indigestion of this type is the result," it is

added, "of long-continued dietetic errors, and in its treatment the dietetic plan marked out above should be adhered to as closely as possible. By way of medication intestinal antisepsis is indicated. For this purpose combinations of chalk, bismuth, magnesia, salol, salicylate of soda and naptbol are valuable. The patient may take after each meal a powder consisting of five grains each of prepared chalk, magnesia, and salol, or five grains each of salicylate of bismuth and naphthol; nux vomica and colombo are also valuable. Diastases often are of service. Either malt or pancreatic diastases may be used. They are to he given during the meal. [They probably act by digesting the starch in the stomach and favoring absorption of the resulting sugar before it reaches the intestine.] Laxatives often prove useful in emptying the bowels of its fermenting contents."

Certain forms of dyspepsia require acids distinctly in their treatment, but this is beyond the province of this paper. *F. Peyre Porcher.*

EAR DISEASES, NOMENCLATURE AND STATISTICS OF. The nomenclature herewith presented is based upon the one prepared and used by the aural surgeons of the Massachusetts Charitable Eye and Ear Infirmary in Boston. Many changes and a goodly number of additions have been made—some in the interest of a scientific nomenclature, others for statistical utility. On the whole it has suffered by these changes, but they were made necessary by the loose method of recording diseases in the various hospital reports, from which the statistical material for this article was gotten. As all additions are in brackets, the original can be seen practically undisturbed.

The statistical portion is based upon a study of 104,412 cases of ear disease, taken from the thirty-two annual reports of the nine eye and ear hospitals, as indicated in the list given at the end of the article. The different nomenclatures followed in these reports, and their inexact records of diseases, have added much to the labor of preparing, and have materially interfered with the scientific accuracy of, this article.

The tables are self-explanatory. Each disease is credited in the first column of figures with the number of cases of such affection found in the grand total of 104,412 tabulated cases, while the second column shows the proportionate frequency of the affection in every thousand cases of ear disease in general. Where the frequency is less than one in a thousand the fraction expressing this small frequency will be omitted altogether.

James Lancelot Minor.

EAR: OPERATIONS UPON THE MIDDLE EAR.

Ever since Sir Astley Cooper, in 1801, improved the hearing of a patient by perforating the membrana tympani, surgical procedures upon the middle ear have afforded a fruitful field for study, speculation, and argument. In no other branch of surgery, probably, have certain procedures been so strenuously advocated for a short time, and, upon further investigation, been found to be disappointing in their results, and consequently abandoned for other measures equally useless. A glance at the history of middle-ear surgery will, I think, partially explain this, by diselosing the fact that every new procedure was employed without proper discrimination, in a large class of eases where more care in defining exactly the indications for the operation would have prevented its performance. It is not strange, therefore, that every advance in this branch of our art is looked upon with suspicion, and that its efficacy must be proven beyond a peradventure

before it is adopted. Clearly before any operative measure can stand this test the indications for its application must be distinctly defined, and the determination of these indications very often proves to be more difficult than the operation itself.

It is evident that operations upon the tympanum can be of benefit only when the pathological process is limited entirely, or almost entirely, to this part of the auditory apparatus, and has not involved the adjoining parts secondarily. To be more clear, we can hope to relieve an impairment of hearing or a distressing tinnitus by operation upon the tympanic structures, only when we are assured, by a careful examination, that the receptive apparatus is in a fairly normal condition, thus locating the disease in the conducting apparatus. Again, if we are questioned as to the probable result of such a procedure in a case of long-standing otorrhœa, it must be determined by careful examination that the bony necrosis is confined to those parts of the middle ear which can be reached by instruments introduced through the meatus; otherwise a complete removal of the affected parts would be impossible, and the result of an operation unsatisfactory.

The above suggestion seems almost unnecessary, but one has only to study the reports of cases operated upon to be convinced that often the exact location of the pathological process was undetermined before the operation.

Operative measures within the middle ear are undertaken:

1. For the improvement of hearing.
2. For the relief of subjective noises, or certain nervous phenomena, such as giddiness, etc.
3. For the relief of a persistent discharge.

Any one of these conditions may exist alone, or all or any two may occur together and demand relief.

As before stated, the success of operative treatment depends primarily upon our ability to locate the pathological process in the tympanum. I shall therefore preface what is to be said concerning the surgery of the tympanum by a few suggestions as to how we are best able to determine that, in any particular case, the middle ear is the part of the auditory apparatus at fault. If the purpose of our operation is to relieve a persistent discharge, careful ocular inspection and manipulation with the probe will enable us, in many instances, to determine the extent of the morbid process; more will be said upon this point when we come to consider the operative methods for the relief of discharge. Most frequently, however, aid is sought for an impairment of the hearing, or a persistent tinnitus, and physical examination alone, in many instances, may mislead us as to the result of operative measures. It is not enough to find, in such a case, that the tympanum is the seat of a chronic inflammation, or that as the result of a preceding inflammatory affection the tympanic structures have been bound down to such an extent that they cannot transmit the sound-waves, but we must be certain that the receptive apparatus is in a fairly normal condition before a favorable prognosis can be given as to the result of relieving the tension of the conducting apparatus by surgical means.

For this determination a series of tuning-forks has been found of great service. In my own work six forks are used, as follows: one, the lowest ($C-^1$) making 32 vibrations per second; the next (C) making 128 vibrations per second; the other four (C^1, C^2, C^3, C^4) being C forks of the next four octaves, the highest registering 2,048 vibrations per second. The last five forks constitute the series used by Hartmann,[1] and are really all that are necessary for determining the probable outcome of operative procedures, although the other fork ($C-^1$) is sometimes of use.

It is well known that any rigidity of the conducting mechanism so alters the relation of air-conduction to bone-conduction that in affections of the middle ear the duration of bone-conduction, as compared with that of air-conduction is increased, and frequently may be greater. Further observation teaches us that the change begins with the lowest notes of the scale, and that as the parts become more rigid the higher notes are affected. Thus in a slight rigidity of the middle-ear mechanism, consequent upon a temporary narrowing of the Eustachian tube, or congestion of the lining of the tympanum, the lowest fork of the series will be heard longer from the mastoid than when held in front of the meatus, while all the other forks may be heard better through the air than through the bone. If now, instead of a slight rigidity, we have the conducting apparatus bound down by adhesions, either as the result of a chronic purulent inflammation (with more or less complete destruction of the membrana tympani) or as the result of a non-suppurative inflammation of long standing, the membrana tympani being present and partaking perhaps in the pathological process, to the extent of being thickened in places, and even adherent here and there to the inner wall of the tympanum, we shall find as the power of audition becomes more and more impaired, that the bone-conduction for the successive higher forks of the scale will gradually become equal to, and at last better than, air-conduction. In other words, the degree of impairment of hearing, and the increased duration of bone-conduction for the higher forks, as compared with air-conduction, always bear a direct relation to each other, if the lesion is located in the conducting apparatus. If the hearing distance for speech was so reduced that loud voice was only heard close to the ear, and the duration of bone-conduction exceeded that of air-conduction for the first two or three octaves only, we should not be justified in locating the lesion in the conducting mechanism alone, but should conclude that the receptive apparatus was affected as well. Especially would such a conclusion be warranted if, in addition to the above, bone-conduction for the fork C^2 was appreciably reduced below the normal standard of bone-conduction, or if the fork C^3 was not heard at all by bone-conduction, or if the fork C^4 was perceived by neither bone- nor air-conduction. In such a case the chances would be that the receptive apparatus had become involved secondarily, and that although an operation might successfully relieve the tension in the transmitting mechanism, this relief might not greatly improve the hearing on account of the condition of the deeper parts, which would be unaffected by operation.

In applying these tests certain facts must be remembered. Thus, the age of the patient plays an important part in the determination of this question. Bone-conduction in individuals past middle life is relatively reduced as compared with this power in youth and early adult life. This has been demonstrated by Urbantschitsch[2] as due to senile torpidity of the auditory nerve, and can be confirmed by any one who makes use of the tuning-fork in a large number of cases. It is also to be remembered that secondary involvement of the receptive apparatus is less likely to have occurred when the cause of the impaired hearing or tinnitus has been a suppurative otitis, than when the tympanic affection has been of the sclerotic form. The duration of the malady is also to be taken into consideration; but as operative measures would only be adopted after all other plans had failed to give relief, this need scarcely be mentioned.

The above tests may be applied equally well to cases in which the membrana tympani has been partially or almost completely destroyed, or when it is intact. Moreover they are not based upon theory, but are deduced from the comparison of the results, after operations, by the author, in a number of cases in which the tests have been made. Almost without exception success or failure could be predicted by a careful study of the results of the tuning-fork examination, and the cases where these tests indicated a probable unfavorable result were subjected to operation only at their own request, that they might be allowed to have every possible chance for improvement, however slight this might be.

Preparations Preliminary to Middle-ear Operations.—While the remarks included under this heading may be, to a certain extent, superfluous, I have resolved to enter into detail, for the reason that I believe the suggestions may be of value to some whose experience in this branch of otology has been limited.

Instruments.—Most of the instrument-makers are pre-

pared to furnish instruments designed for this special work; many of the instruments are designed for the purpose of performing one particular operation, and usually have been modelled according to the idea of some one individual operator, and represent his personal preferences. It should be remembered, however, in this branch, as in general surgery, that individual preference for any one instrument does not of necessity indicate that it alone is adapted to the special procedure; but simply that in the hands of one familiar with its use it

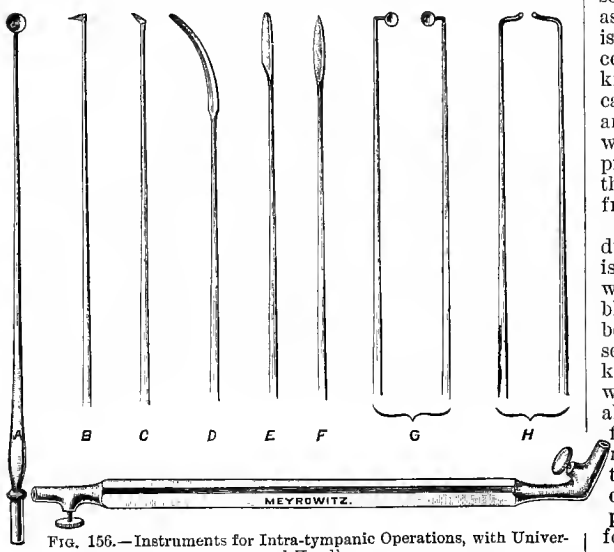

Fig. 156.—Instruments for Intra-tympanic Operations, with Universal Handle.

has served a good purpose. Every operator will, from habit, develop a preference for a special device, and in his hands it undoubtedly is more serviceable than any other, but the aural surgeon upon entering the operative field should first obtain a clear idea of what is to be accomplished, and then choose those instruments which seem to him best adapted to carry out the procedure. In a general way, then, the armamentarium should include in addition to the ordinary instruments used in diagnosis and treatment, delicate knives, both sharp- and probe-pointed, and both curved and straight; knives curved on the flat, angular knives, the blade making an obtuse angle with the shaft, or a right angle, according

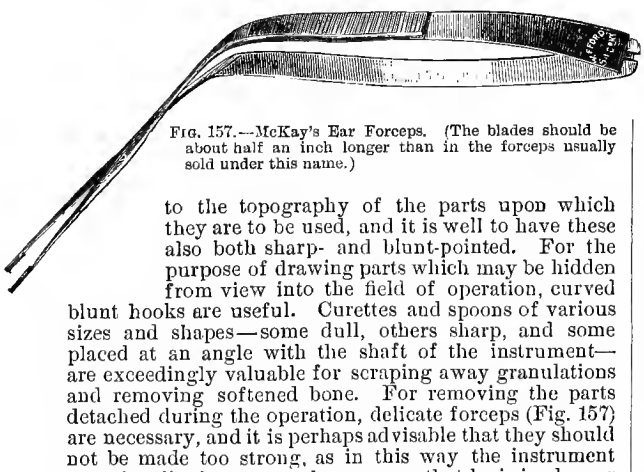

Fig. 157.—McKay's Ear Forceps. (The blades should be about half an inch longer than in the forceps usually sold under this name.)

to the topography of the parts upon which they are to be used, and it is well to have these also both sharp- and blunt-pointed. For the purpose of drawing parts which may be hidden from view into the field of operation, curved blunt hooks are useful. Curettes and spoons of various sizes and shapes—some dull, others sharp, and some placed at an angle with the shaft of the instrument—are exceedingly valuable for scraping away granulations and removing softened bone. For removing the parts detached during the operation, delicate forceps (Fig. 157) are necessary, and it is perhaps advisable that they should not be made too strong, as in this way the instrument may, by slipping, warn the surgeon that he is in danger of using too much violence. A good aural snare is also a convenient instrument to have at hand. As to whether the instruments should be mounted upon straight or angular handles is again a matter of personal preference. For my own use I prefer to have most of the instruments so modelled that the shaft forms an angle of 30 to 45 degrees with the handle; but as it is sometimes more convenient to use a straight instrument, it is well, in case the universal handle is to be used, to have one extremity adapted to receive the instrument at an angle, while by fitting the knife into the other end of the handle a straight instrument is obtained (see Fig. 156). For rapid operative work it is better to have each instrument in a separate handle, but as this increases the bulk of the case, as well as the cost of the instruments, the universal handle is often used. Of late I have made use of the excellent suggestion of Prout,[3] that the shank of the knife be left untempered, and in this manner its shape can be changed at will. Knives made in this way, and provided with simple octagonal metal handles, into which the shaft screws, can be obtained at a much less price than those of a more elaborate design, and as from their extreme delicacy instruments of this kind must be frequently replaced, this form certainly commends itself.

At any operation all cutting instruments should be duplicated, and even a greater number of each variety is an advantage, as they soon become too dull for delicate work. It is important that in all knives the back of the blade should be of sufficient thickness to permit of its being honed to a very fine edge; it being impossible to secure a keen cutting edge in a very thin knife. All knives should be as sharp as skill can make them, and when even slightly dull should be laid aside. It seems absurd to state this, but I have frequently had great difficulty in impressing its importance upon instrument-makers, and consider it a point of the greatest importance. The structures to be divided are extremely delicate, and unless the blade be very keen, may often be pushed aside by the knife, instead of divided, or undue force may be necessary in order to effect section, and important structures may thus be damaged. Again, the field of operation being small, any failure to expose the parts as fully as possible, or the production of hemorrhage by harsh manipulation, seriously hampers the operator.

Immediately before the operation all instruments to be used should be sterilized by submersion in boiling water or exposure to steam for about ten minutes.

Preparation of the Field of Operation.—In order to diminish the probabilities of suppuration, and reduce the reaction to a minimum, the field of operation should be rendered as aseptic as possible. In cases where there is no discharge from the ear, and the canal is clean, there is very little danger of infection from this source. It is safer, however, to order that the ear be syringed with a solution of bichloride of mercury, 1 to 5,000, twice daily for several days before the operation, and that after each syringing the canal be closed by a pledget of aseptic cotton. Of course, any cerumen or dead epithelium which may have collected in the canal must be thoroughly removed before the syringing is done. Upon the day of the operation the ear is not to be syringed, owing to the congestion which it causes; Blake[4] suggests that it may be wiped out by means of a pledget of cotton saturated with the antiseptic solution.

In cases where there is discharge, the previous cleansing of the ear is of great importance, especially if there is to be any interference with the stapes, since infection of the labyrinth is among the possibilities. In all cases, therefore, where there is a purulent discharge, provided any operation is to be done beyond the simple division of adhesions, the ear should be syringed several times daily with an antiseptic solution in the manner already described. It is true that in many cases no harm comes from operating without carrying out these measures, but it is only our duty to protect the patient in every possible way.

When the middle ear has been the seat of a long-continued suppurative process, we usually find considerable granulation tissue within the tympanum, or, if this is not the case, the remnants of the drum membrane, as a result of chronic myringitis, are much thickened, and richly

supplied with blood-vessels, bleeding freely upon the slightest violence. It is often advisable in such cases to employ a certain amount of local treatment before the operation, in order to reduce the turgescence and render the operation more simple.

Anæsthesia.—As to the question of anæsthesia only general rules can be given. In general it may be stated that as these operations require exceedingly nice manipulation for their performance, and it is necessary for the patient to remain absolutely quiet, general anæsthesia is in most cases preferable, and in many absolutely necessary.

For the division of adhesions in old purulent cases, in which there is a large exposure of the tympanic cavity, the introduction of a few drops of a strong solution of cocaine will usually render the operation endurable in patients who have a fair command of themselves. In these cases it is often necessary to do repeated operations on successive days, each one occupying but a few seconds, and in such cases general anæsthesia would cause the patient more annoyance than the procedure itself.

Usually where the membrana tympani is present and we wish to enter the tympanic cavity for purposes of thorough exploration and subsequent operation, a general anæsthetic must be administered. If possible, however, it is advantageous to make the exploratory incision by means of local anæsthesia, as we can then determine the effect upon the hearing, and subsequently induce general anæsthesia for the purpose of conducting any further procedures which may be necessary. For the production of local anæsthesia I have used a ten per cent. ointment of cocaine and lanolin. A small quantity is smeared on a pledget of cotton, placed in contact with the membrana tympani and allowed to remain for about ten or fifteen minutes. A certain amount of anæsthesia is gained in this way. After the membrana tympani has been incised, a drop of a ten per cent. solution of cocaine in the tympanic cavity will produce a very decided anæsthesia.

Miot[5] claims that he has been able to carry on very extensive manipulation of the intra-tympanic structures by instillation of cocaine after incising the membrana tympani. Although the actual pain of these procedures is not great, the tax upon the nerves of the patient is severe, and much will depend upon the self-control of the individual. I have found the anæsthesia following the use of the lanolin and cocaine ointment, and the instillation of an aqueous solution of cocaine after the first incision, amply sufficient to remove the cicatricial membrana tympani which often forms after excision of the membrana, malleus, and incus. As all the cases operated upon by this method have been delicate females, I am inclined to think that the procedure has not been attended with much pain, as they scarcely complained.

Cholewa[6] has obtained excellent results from the use of strong solutions of aluminium aceto-tartrate as a local anæsthetic in this region, but I have no personal experience with the method. In general, I should restrict local anæsthesia to the division of adhesions in cases where the tympanum is freely exposed as the result of a previous purulent inflammation, or when the parts are covered by a thin cicatricial membrane only, or where they are endowed with slight sensibility; to partial myringectomy by chemical agents; and to exploratory myringotomy. In all other cases I decidedly prefer general anæsthesia, and in my own hands ether has been the agent employed exclusively. If the ordinary rules for preparing a patient for ether, such as attention to the food taken upon the day of operation, the condition of the bowels, etc., are attended to, the unpleasant effect of the drug is in a large measure avoided, and is rarely very disagreeable.

Position of the Patient.—As we habitually inspect the ear with the patient in the upright or semi-recumbent position, the operator is placed at a decided disadvantage if the horizontal position is employed at the time of operation. Another disadvantage of this position is that with the head low, or only slightly elevated, hemorrhage is much more profuse, and the field of operation more obscured, especially that portion of the field in which lie the structures of the greatest importance, the upper and posterior part, the blood collecting in this situation in obedience to the laws of gravity. A still further objection lies in the fact that if the ossicles are to be removed, the horizontal position favors the dislocation of the incus toward the mastoid antrum. For the comfort of the surgeon the head should be in such a position that it can be easily turned in all directions without the operator's manipulations being in the least interfered with. For all of these reasons I now always operate with the patient in the semi-recumbent position. This is easily secured by means of the head-and-shoulder rest shown in Fig. 158. This device is clamped to any convenient table, or to a bed, the head-rest is removed, the shoulder-frame let down, and the patient is anæsthetized in the horizontal position, care being taken that the shoulders are well up on the frame. When complete anæsthesia has supervened, the shoulder-rest is elevated to the required height and held in place by the ratchet, as seen in the figure. The head-rest is placed in position and supports the occiput. As the head-piece is supplied with a ball-and-socket joint, the head can be placed in any desired position, and maintained by turning a screw which renders the joint immovable. Straps passed under the arms prevent the body from sliding downward; elevating the foot of the table or couch also serves the same purpose. By this simple device the head is as completely

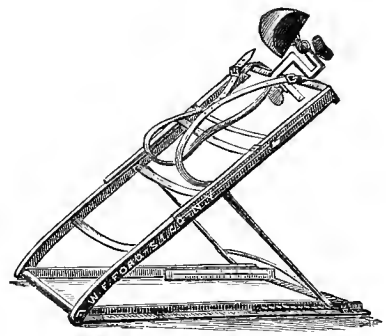

FIG. 158.—Head-and-shoulder Rest.

under the control of the operator as when the patient is conscious, and the surgeon can manipulate from all sides, his movements not being interfered with by the patient's shoulders, the edge of the table or other obstacles. Anæsthesia is maintained in this posture with no more difficulty than with the patient in the ordinary position.

Illumination.—Many prefer daylight for all work upon the middle ear, and there can be no doubt that a perfect north light affords an ideal source of illumination. The great objection to natural light is its uncertainty. For this reason I have never used it extensively, even in the examination of patients, and have become accustomed to make use of the ordinary argand gas-burner. The slight yellow tinge of the gas-flame modifies the appearance somewhat, but if used to the exclusion of other sources of illumination, of course does not mislead. When general anæsthesia is resorted to, the gas-flame becomes objectionable on account of the danger of igniting the ether, and if it is removed to such a distance that there is no danger, its rays, reflected from the surface of the head-mirror, are scarcely powerful enough for fine operative work. If great care is used the gas-burner may be brought near enough to furnish sufficient light; it should never be less than five feet away from the inhaler, and at a somewhat higher level. As an additional precaution, the face of the patient, and the inhaler also, should be covered with a wet towel. Since the use of storage batteries has become general, the incandescent electric lamp has been much used, and undoubtedly affords the most convenient source of illumination. The lamp is usually placed in a cylinder, one end of which is provided with a double convex lens for rendering the rays convergent, while behind the lamp is placed a metal

reflector, which serves to direct all the rays through the lens. The apparatus may be worn upon the head by means of the ordinary head-band, or may be mounted upon a standard, and the head-mirror used in the usual way to illuminate the field of operation. If the first method is adopted the lens should have such a curvature as to bring the rays to a focus at a point about six or seven inches in front of the apparatus, while if the head-mirror is used the rays should simply be rendered parallel. As I habitually make use of the perforation in the head-mirror, I prefer to use the latter method; this is simply a matter of personal preference, however. The use of the electric lamp does away with all fear of accident from ignition of the ether, and permits the surgeon to give his entire attention to the operation.

Classification of Operations.—The various operations which have from time to time been suggested and performed upon the middle ear are quite numerous. While I do not propose to give a full history of all of these surgical procedures, it may be wise to mention them briefly, dwelling at length only upon those which seem to be of undoubted value. We may classify these measures as follows:

1. Operations involving the membrana tympani alone, under which are to be considered:

(*a*) Perforation of the membrana (myringotomy).

(*b*) Excision or destruction of a portion of the membrana for the purpose of establishing a permanent opening (partial myringectomy).

(*c*) Single or multiple incisions through the membrana for correction of anomalies in tension. (Under this head we include division of the posterior fold, or plicotomy.)

2. Operations involving the soft parts within the tympanum, under which we include:

(*a*) Tenotomy of the tensor tympani muscle.

(*b*) Tenotomy of the stapedius muscle.

(*c*) Section of the anterior ligament of the malleus.

(*d*) The division of adhesions, the result of suppurative or non-suppurative inflammation.

3. Operations involving the ossicular chain, comprising:

(*a*) Excision of a portion of the malleus.

(*b*) Disarticulation of the incudo-stapedial articulation, or division of the long arm of the incus and mobilization of the stapes.

(*c*) Plastic operations for the purpose of uniting either the incus or stapes with the membrana tympani.

(*d*) Removal of the ossicular chain in its entirety, or the excision of individual ossicles.

1. *Operations Involving the Membrana Tympani Alone.*

(*a*) *Myringotomy.*—Puncture of the tympanic membrane became a recognized surgical procedure chiefly through the investigations of Sir Astley Cooper.[7] Performed primarily for the improvement of hearing, it was found that it was of permanent benefit only in those cases in which the hearing had been impaired by collections of fluid within the tympanum. Its efficacy in such cases has been already discussed in the portion of this work devoted to otitis media, and need not be commented upon here. Under other conditions, closure of the opening by cicatrization reduced the hearing to its former condition.

To us incision of the membrana tympani is of use not only for the evacuation of fluids, but as affording us a means of exploring the tympanic cavity, and determining the mobility of the stapes in cases where adhesions have formed within the middle ear.

Schwartze[8] recommended the excision of a portion of the membrane for the purpose of determining the mobility of the stapes, while De Rossi[9] advises the formation of a flap from the membrana tympani, and after turning it aside to fully test the mobility of the ossicles.

It should be remembered that an operation through the membrana enables us not only to test the mobility of the ossicular chain by means of a probe, but if the operation is performed without the use of a general anæsthetic, and this is often possible, we are able to observe the effect of the artificial opening upon the hearing. In cases of thickening of the membrana tympani itself, or when it has become much relaxed, and by its own weight acts as a load to the conducting mechanism, the hearing will improve after the perforation. It also gives us some information as to the condition of the membrane covering the round window, since the artificial opening allows the sound-waves to impinge directly upon this part. Exploratory incision, then, is, in certain cases, of aid in informing us how much of the impairment in hearing is due to the presence of the membrana tympani and also the extent of the rigidity of the stapes. It is of special diagnostic value in cases of tympanic sclerosis, resulting from non-purulent inflammation, in which the receptive apparatus is involved secondarily. In such a case the probable outcome of surgical interference can sometimes be determined by exploratory myringotomy, since if the stapes were found movable, and the hearing is not improved by the artificial opening, very little could be expected from further operative procedures. In a case of this kind, in which this opinion had been arrived at by means of the tuning-fork tests, an exploratory incision enabled me to confirm the diagnosis, and advise against further operative interference.

Steps of the Operation.—In the cases in which such an incision is likely to be required, the membrana tympani, as the result of the preceding inflammation, has usually lost much of its normal sensibility; but if the impact of a probe causes pain it is well to place a pledget of cotton saturated with a ten per cent. cocaine lanolin ointment against it for a few minutes before operating. With a sharp knife a curved incision is to be made from the lower border of the membrana flaccida downward, directly over the incudo-stapedial articulation if this is in view, otherwise the incision is to be made close to the posterior margin of the tympanic ring. The incision is to be parallel to the periphery of the membrana tympani, and should extend downward nearly to the level of the tip of the long process of the malleus. Usually the edges of the wound retract enough to permit the articulation to be seen, and the mobility of the parts to be tested by means of a probe; if not, a second incision may be made from the upper extremity of the first, and carried toward the short process of the malleus, until a sufficiently large flap is formed to permit of the exposure of the articulation. The upper incision should lie just below the border of the membrana flaccida; should this membrane be incised, the resulting hemorrhage might obscure the field of operation, while if the section is made as directed above, and care is taken not to wound the inner wall of the tympanum, no blood will be lost and the exposed parts will be clearly seen. The mobility of the stapes can now be tested by means of a fine probe passed through this opening. Any effect upon the hearing should also be noted. If further operative steps are deemed unadvisable, the edges of the incision should be approximated with the cotton-tipped probe, and a pledget of sterilized cotton adjusted against the membrane. In case of a simple incision the insufflation of a little boric acid is usually all that is necessary.

(*b*) *Partial Myringectomy.*—For the purpose of establishing a permanent opening in the membrana tympani various methods have been resorted to, such as excision of a portion of the membrane as advised by Gruber,[10] destruction of the membrane over a limited area by means of the actual cautery, as advocated by Voltolini,[11] or by a chemical caustic, as practised by Simrock.[12] Schermunsky[13] advises that a crucial incision be made in the membrane at the desired location, and that the edges of the wound be then cauterized with chromic acid. According to this author, a permanent opening will be left upon the separation of the eschar caused by the chromic acid.

In my own hands this method has proved as useless as the others, and it has been the experience of all otologists who have attempted this procedure, that in most instances the opening closes, though in some cases the interval is very long. To maintain a permanent opening, Politzer[14] advised the insertion of a vulcanite eyelet into the perforation made either with the galvano-cautery or

with the knife. Experience has proved that even this method is ineffectual, and it has fallen into disuse.

The only cases in which I can conceive of partial myringectomy as being advisable are those in which further operative measures are to be employed, in case an opening in the membrane improves the hearing. Here I believe that all the indications are better met by the exploratory myringotomy already described. In one case in which I attempted to establish a permanent opening in the membrane, the method of Simrock was employed, and as this seems to be rather simpler than the other procedures I will describe it in detail.

A minute drop of concentrated sulphuric acid is carried into the canal on a cotton-tipped probe, and held against the membrane at the point where the perforation is to be made, care being taken not to touch the canal at any point. The acid at once destroys the membrane over the area touched, and perforation is readily effected by means of a blunt probe. In my own case very little reaction followed, and I am inclined to believe that the method accomplishes the purpose quite as well as the more complicated procedures. After the perforation has been made, the parts should be kept clean, either with the cotton pledget, or, in case a profuse discharge supervenes, the syringe may be used, although the less the parts are manipulated the longer the perforation remains, as a rule.

(*c*) *Multiple Incision of the Membrana Tympani.*—This operation has been advocated both by Politzer[15] and by Gruber,[16] but, curiously enough, for exactly opposite conditions. Politzer recommends the procedure in cases when the membrana tympani is much relaxed, the result of the cicatrization of a large perforation, believing that the contraction following the healing of the incisions will correct the relaxation. In his hands the operation has met with a certain amount of success. On the other hand, Gruber finds that when the membrane has become tense or rigid from a chronic inflammatory process that several incisions made through it will, upon healing, relax the abnormal tension, and permit the parts to perform their functions more properly. Gruber advises that the incisions be made from the centre toward the periphery, through the dense portions of the membrane, the adjacent lines of section being connected by transverse incisions, somewhat in the form of the letter H.

I have had no experience with this procedure, and should be inclined to believe that when the operation was performed for relaxation the improvement would be at the most but temporary. The method of performing the operation must of course vary in each individual case; care should be taken that the inner wall of the tympanum is not wounded by the point of the knife, as any bleeding would obscure the subsequent steps. Cicatrices of the membrane are only slightly sensitive, and the incision of a membrane thickened by a chronic myringitis is also usually much less painful than when the membrane is normal; hence in an intelligent patient general anæsthesia is seldom necessary, although it would be advisable to employ it if the patient is nervous.

Plicotomy.—Division of the posterior fold of the membrana tympani was proposed by Politzer[17] and by Lucae[18] at about the same time. This measure was recommended when the membrana tympani was much retracted, the short process and posterior fold being very prominent. In such cases the contraction of the fibres of connective tissue forming the posterior fold increases the tension of the conducting apparatus, and interference with function is the result.

The operation consists in the division of this fold by an incision midway between the short process and the peripheral extremity of the fold and perpendicular to the direction of the fold. Either the sharp-pointed knife may be used, or, as Politzer advises, the extremity of the instrument may be rounded, so as to diminish the danger of dividing the deeper structures. The same author advises that the incision be made from above downward. Gruber[19] has found better results from incising the fold longitudinally. In either case, if the operation has the desired effect, the manubrium will assume a less horizontal position, showing that the tension has been relieved. The immediate effect seems to have been to diminish the subjective noises, and in some cases to improve the hearing, but the improvement has almost always been temporary. My own experience has been limited to but one case, and here no improvement resulted. The operation is devoid of danger; if the chorda tympani is wounded the effect upon the sense of taste will be but transitory, and with proper care suppuration should not follow the operation. It is well to allow the wound to heal slowly, and for this purpose daily inflations for a few days after the section has been made may be practised. Locally, the insufflation of a minute quantity of boric acid is probably the best treatment for the wound. The operation is so uncertain in its results that it cannot be strongly advocated, since it will be the exception to find the increase in tension limited to the posterior fold. Usually the presence of similar constricting bands in other parts of the tympanum render the outcome of the procedure unsatisfactory.

The next group in our classification comprises:

2. *Operations in which Various Muscular or Fibrous Structures within the Tympanum are Divided.*

(*a*) *Tenotomy of the Tensor Tympani Muscle.*—This operation was proposed by Hyrtl,[20] but was first performed upon the living subject as a therapeutic measure by F. E. Weber.[21] The indications for performing this operation have never been definitely given, as it is manifestly impossible to be certain that in a given case the increased tension of the conducting apparatus depends entirely upon a shortening of the tensor tympani muscle. The most prominent indication for its performance seems to be a temporary improvement of the hearing or relief of tinnitus immediately after inflation, the symptoms soon reappearing, however, as the membrane becomes depressed. It is argued that in such cases the muscle has become permanently shortened, either by participation in the tympanic inflammation or from the fact that, on account of Eustachian obstruction of long duration, the aeration of the tympanum has been imperfect and the membrane sinks inward upon the promontory. The function of the tensor is thus ablated, and the muscle soon becomes atrophied from disuse and is converted into a tense fibrous band which prevents the membrane from resuming a permanent normal position, even when the patency of the tube is restored. In addition to this, it is supposed that by the tension of the muscle the manubrium is pressed upon the inner wall of the tympanum with considerable force, thus mechanically adding to the inflammatory process already present in the middle ear. It will be seen that if such is really the case a division of the tendon of the muscle would remove one of the causes of the tympanic inflammation. Since the operation was first proposed valuable contributions to the subject have been made by Green,[22] Pomeroy,[23] Hartmann,[24] Schwartze,[25] Cholewa,[26] and Müller.[27] It is hardly necessary to say that in addition to the objective signs already given, as indicating the advisability of the operation, the result of the tuning-fork tests should also be considered and should indicate unquestionably a lesion of the conducting apparatus as the prominent pathological condition. Cholewa states that the forks C and C^1 should be heard at least eight seconds by bone-conduction, and that the air-conduction for the forks C^1, C^2, C^3, C^4, should not fall much below one-fourth the normal duration of air-conduction for these tones.

Steps of the Operation.—Most authors agree that general anæsthesia is seldom necessary, and Cholewa states that in many of these cases the sensibility of the membrana tympani is much diminished. The same author advocates the induction of local anæsthesia by strong solutions of aluminium aceto-tartrate or by ether, a pledget of cotton saturated with the agent being placed in contact with the membrane and the fluid allowed to evaporate. The ointment of cocaine and lanolin may also be used in the same manner. In the very few cases in which I have resorted to this measure it was rather difficult to control the patient as perfectly as might have been desired, and I believe

that a general anæsthetic will add much to the completeness of the operation.

With reference to the method of dividing the tendon there is considerable difference of opinion. Weber-Liel and Cholewa have advised that it be accomplished by the introduction of the knife in front of the short process of the malleus. Both of these operators have devised special instruments for the purpose, differing from each other only in the shape of the blade. These instruments were constructed in such a way that the hook-shaped knife could be rotated upon the long axis of its shaft by sliding a button upon the handle. The technique with an instrument of this kind is as follows: The membrana tympani is incised just in front of the processus brevis, the hook-knife introduced into the tympanic cavity, and by depressing the handle of the instrument and carrying it somewhat forward the blade is made to press upon and partially encircle the tendon; by sliding the button upon the handle downward the hook-blade is rotated, thus dividing the tendon; by again manipulating the slide the blade assumes its original position and the instrument is carefully withdrawn from the tympanic cavity; a forcible inflation and the insufflation of a little boric acid to cover the wound complete the procedure.

Much simpler are the methods of Schwartze, Hartmann, Gruber, Pomeroy, Green, and Urbantschitsch, who divide the tendon without the aid of the complicated instrument above described. With the exception of Gruber,[28] all of the above writers prefer entering the tympanic cavity behind the malleus handle, and Gruber states that in some cases, where the anterior segment is very small, this may be advisable. Almost every operator has devised a special instrument which, in his hands, has appeared more satisfactory than any other, from which we may infer that, bearing in mind the anatomy of the parts, almost any instrument with the blade curved on the flat may be used for the purpose. Schwartze, Pomeroy, and Green prefer a blunt knife, curved on the flat, similar to that represented in Fig. 156, *D*, with the exception that the curve should be a little sharper than represented. Gruber's knife is less curved and is pointed. Hartmann's knife is pointed, and, in addition to the curve on the flat, the sharp point is curved upward, so that when the knife is inserted the point passes well up into the tympanic cavity. Urbantschitsch[29] uses a knife with a double cutting edge, the blade being short and making an obtuse angle with the shaft; an instrument similar to that shown in Fig. 1, *C*, with the exception that it is blunt instead of sharp.

The position of the puncture and the manipulation of the instrument after the blade has entered the tympanic cavity will vary according as the tendon is to be divided from above downward, or from below upward; and here again I believe the operator should be allowed a certain amount of latitude, depending upon the conformation of the parts in each special case. If the division is to be made from above downward, as advised by Schwartze and Urbantschitsch, the membrana tympani is punctured immediately behind the short process, and the curved or angular blade of the knife is carried high up into the tympanic cavity by depressing the proximal end of the instrument, which at the same time should be carried a little backward, thus causing the blade to apply itself closely to the malleus. The blade is then rotated forward and downward through an angle of 90°, the tendon being severed by a slight sawing motion, and by pressing the knife downward, at the same time withdrawing it. As the tendon is divided the operator feels the resistance which it offered suddenly overcome, and frequently a sharp snap is heard at the moment of division.

Hartmann and Pomeroy divide the tendon from below upward. Hartmann advises that the membrane be incised just below and behind the short process; upon entering the tympanic cavity the knife is advanced forward, inward, and slightly downward, the shaft remaining almost horizontal and the flat surface of the blade being close to the handle of the malleus until the blade has nearly traversed the breadth of the tympanic cavity, when the handle is depressed, thus carrying the curved point of the knife high up in the tympanum; the instrument is then withdrawn, upward pressure being continually exerted, and the tendon is divided from below upward. Just before the tip of the knife emerges from the tympanum, the handle is elevated to avoid injury to the parts in the region of the posterior fold. Pomeroy[30] first punctures the membrane behind the manubrium and near its tip, and then introduces a blunt curved knife, with its concave side looking forward and being closely applied to the handle of the malleus. The tendon is divided by depressing the handle of the knife and extending the incision upward to the short process.

Green[31] enters the tympanic cavity with a myringotome, behind and below the short process of the malleus, and extends the incision upward to the margin of the ring. Through this incision the curved blunt knife is introduced and the tendon located; it is divided either from above downward, or in the opposite direction, according to its attachment in each individual case.

When it seems desirable to divide the tendon by an incision through the anterior segment of the membrana tympani, the curved knife is to be carried through the membrane somewhat below the short process, the concavity of the knife looking backward. On entering the cavity the instrument is advanced upward and backward, keeping the blade closely applied to the malleus handle. The tendon is thus divided from below upward. Whatever method is used to effect a division of the tendon, the after-treatment consists in a forcible inflation by means of the catheter or Politzer's method, after which the incision is covered with a little boric acid and the wound allowed to heal.

Results.—The immediate effect of the operation is usually to diminish the subjective noises, and in some cases the hearing improves. It has been the experience of many observers, however, that the good results have been but temporary, and that after an interval the symptoms have reappeared. This may be explained by the reunion of the cut ends of the tendon, or by the invasion of other parts of the conducting apparatus by the pathological process. My own experience with the operation has been limited to a few cases, in which the tendon was divided for the relief of tinnitus. In one case there was considerable improvement; in the others the final result is not known, but immediately after the operation there was no improvement. In making the section I ordinarily use the curved knife (Fig. 156, *D*), the membrane being first incised with a pointed knife, either in front or behind the manubrium, according to the shape of the canal and the amount of retraction present.

I am not enthusiastic over the operation, for the reason that it is absolutely impossible in any given case to be certain that the tensor tendon is the only intra-tympanic structure affected. While our methods of determining that a lesion is located in the conducting apparatus are fairly perfect, we have no means as yet of assuring ourselves that the increased tension is due to a shortening of the tensor tympani tendon alone. My own choice, when operative measures are necessary, is usually for a procedure which corrects the increased tension, no matter in what portion of the mechanism it is located. Of late the operation has been again brought to the notice of the profession by Cholewa[32] and Müller.[33] Cholewa strongly advises its performance in the cases variously called sclerotic, proliferative, or insidious, not only from the effect upon the ear operated upon, but also for the improvement which he claims often results in the opposite ear. The poorer ear is always the one operated upon first, and even when its condition is not much improved, this author has found in many cases a remarkable improvement in function upon the opposite side. I shall allude to this later, in describing my own experience in cases of ossiculectomy.

Müller advocates the operation in cases of purulent inflammation, in which the discharge continues in spite of careful cleansing and local applications. He believes that the contracted tendon, by crowding the articular surfaces of the ossicles together and binding them to the tympanic wall, is a prominent factor in keeping up the inflammation.

He reports a number of cases in which tenotomy was followed by a rapid cessation of the discharge. The effect upon the function of the organ and upon subjective noises was also satisfactory.

(*b*) *Tenotomy of the Stapedius.*—Division of the stapedius tendon alone scarcely deserves a place among the operations, since when this muscle needs to be divided the section of its tendon is only one step in operative procedures to free the stapes. With the other portions of the conducting mechanism normal, I can conceive of no condition which would indicate tenotomy of this muscle. Accordingly the description of the procedure will be given under those operations of which it really forms a part.

(*c*) *Division of the Anterior Ligament of the Malleus.*—This measure was advised by Politzer [34] in cases of marked retraction of the membrana tympani. It was found that, even after section of the tendon of the tensor tympani, the membrane in some cases would not retain its normal position upon inflation. If, however, the ligamentous structures of the anterior fold were divided the membrane could be made to resume its normal position. The operation consists in puncturing the membrane just in front of the short process with a short curved knife, carrying it nearly to the inner wall of the tympanum; the handle is then depressed and the knife withdrawn, thus dividing the tissues in the anterior fold. In the cases in which this operation was performed by Politzer there was considerable relief to tinnitus, and the hearing was somewhat improved. The objection to the operation is the same as that mentioned in tenotomy of the tensor tympani, viz., that we are never certain that the increased tension is entirely dependent upon the anterior ligament. The procedure may, however, be made use of in cases of tinnitus, with but slight impairment of the hearing, in which more radical measures might be considered a menace to the auditory function.

(*d*) *The Division of Adhesions, the Result of Suppurative or Non-suppurative Inflammation.*—Under this general head we include a large number of procedures, differing from each other according to the precise local condition met with in the individual case. As the stapes is the part of the ossicular chain whose motion is a necessity to useful audition, the ultimate aim of all our efforts is to render motion of this ossicle possible. We have then two classes of cases:

1. Those in which the rigidity depends upon adhesions about the stapes itself.

2. Cases in which the rigidity is caused by adhesion of the malleus or incus to the inner tympanic wall, or by tense bands immobilizing the entire ossicular chain, the articulations between the various ossicles being intact.

Naturally these conditions are more pronounced in cases of old purulent inflammation, although the same condition may obtain in cases of non-purulent otitis. It scarcely need be stated here that a diagnosis is much more simple in cases arising from a purulent inflammation, as the result of which the membrana tympani is largely wanting, enabling the surgeon to see the location of the constricting bands, and to manipulate the parts with the probe, than in those cases in which the deeper parts must be viewed through the membrane, or if this is too opaque, through an artificial opening made for this purpose. It follows that operative measures of this character are much more successful in purulent cases than in the other variety.

When the rigidity depends upon adhesions about the stapes itself, as a result of a purulent otitis, the incudo-stapedial articulation having been destroyed, we find the region of the oval window occupied by a mass of dense tissue, which frequently completely changes the appearance of the parts. Not infrequently the head of the bone is so buried as to be distinguishable only as a slight elevation upon the surface of the mass. Close inspection may reveal a preponderance of the newly formed tissue toward the posterior aspect of the region of the window. This is ordinarily due to the deposit about the stapedius tendon which sometimes can be seen as a bright line running through this mass. To free the stapes (or what is left of this ossicle) in such a case I usually first incise directly downward close to the tympanic ring, so as to divide any bands which tend to pull the stapes out of the field of vision. In making this incision it is important that the knife be carried inward until the inner tympanic wall is encountered, and that in the downward stroke all the tissues be completely severed throughout their entire depth, otherwise some fibres of the stapedius may remain undivided, and pull the stapes out of view. The knife is next carried entirely around the area believed to be occupied by the stapes, thus freeing it from adhesions above, below, and anteriorly. When the knife is carried inward until the bony wall of the tympanum is encountered, care must be taken not to insert it so deeply that, in case the entire stapes has come away, the labyrinth will be wounded. Taking the region of the oval window as a centre, several short radiating incisions are next made to permit the tissues to retract from the oval window; the local depletion thus obtained is also an advantage, as it favors the rapid formation of a thin cicatricial membrane in place of a thick one. After the operation a little boric acid may be insufflated, and syringing should be avoided if possible, as moisture is objectionable.

Frequently this procedure has to be repeated several times, for the process of cicatrization may partially reproduce the old condition, but by repeated incision, dividing the parts most tense, favorable results usually follow in a large proportion of cases. Of course here, as in other conditions, the tuning-forks should be used to locate the seat of the lesion in the conducting apparatus.

In the second class of cases, where the motion of the stapes is impeded by pressure from other parts of the conducting apparatus, which are bound down by adhesions, relaxation of the tension of these parts frequently effects an improvement. Thus we frequently meet with cases in which there is a large perforation, involving the inferior half of the membrane; the edges of the membrane may adhere to the promontory throughout their extent, or the adhesion may be confined to the region of the manubrium. In this latter instance I usually separate the structures with the flat curved knife (Fig. 156, *D*), although Politzer [36] prefers to make vertical incisions through the cicatrix. In either case adhesions reform, but the tension is lessened, and improvement usually results. It is in such cases that Müller [36] advises division of the tensor tympani muscle.

In still another class of cases, with considerable destruction of the membrana tympani, the remnant of membrane in the upper and posterior quadrant will be found thickened and tense, its lower border forming a dense fibrous band, which binds the underlying structures firmly together, and may partially or completely hide the stapes or incudo-stapedial articulation from view. Dividing this band by an incision upward will frequently improve the hearing, or in exposing the stapes may reveal a condition here amenable to operation.

Examples of all of these different conditions have come under my own observation, and the results have always been gratifying. A few of these cases were reported some time since,[37] and subsequently I have met with many more cases in which the results have been gratifying.

When adhesive processes are the result of the so-called otitis media insidiosa, the division of adhesions is not followed by such good results, for the simple reason that when divided through an artificial opening in the membrana tympani, any bands which reform during the process of healing can only be attacked by reopening the tympanic cavity, in fact, by repeating the original operation. While in the class already considered the operative field is always open to inspection, and the operative interference may be undertaken at intervals, according to indication, in the cases we are now considering, the ultimate success or failure depends entirely upon the single operation, and the result of faulty cicatrization cannot be corrected. Still in certain instances the division of adhesions has been of benefit in this class of cases. Thus De Rossi [38] reports a case in which, after turning

down a flap from the membrana tympani, a fibrous band between the malleus and incus was divided. The flap was replaced and held in position by means of a cotton pledget. The patient was much improved by the operation. Prout [39] operated upon a case in which the membrana tympani about the tip of the malleus was adherent to the inner tympanic wall. The instrument used resembled the knife shown in Fig. 1, *C*. By this means the adhesion was divided, that portion of the membrana which was adherent being cut away and either removed or left adherent to the inner tympanic wall. A permanent perforation resulted and the hearing was permanently improved.

While I am heartily in favor of these procedures in cases dependent upon suppuration, I believe that they are to be advised only in special instances where there has been no suppuration. When upon an exploratory myringotomy a condition is found, as in De Rossi's case, which is sufficient to explain all the symptoms, and in which a single operation promises every prospect of success, the simple division of the existing adhesion is all that is indicated. Most frequently, however, we find that the rigidity does not depend upon such a cause, but that the ossicular chain can be rendered normally movable only by the division of adhesions in several localities, especially about the stapes, and so located that subsequent cicatrization is almost certain to result in a return, to a certain extent, of the former local condition. In such cases I prefer to remove the membrana tympani, malleus, and incus at once, the field of operation being then accessible for further measures in case of necessity. My reason for this is that when the membrana is intact, a prolonged intra-tympanic operation necessitates general anæsthesia in most cases, and this cannot be resorted to again and again on account of the discomfort to the patient which it entails. With the tympanic cavity open, as in purulent cases, or after removal of the membrane, malleus, and incus, local anæsthesia by means of a solution of cocaine suffices for all operative procedures of this kind. Hence in any non-suppurative case where general anæsthesia is to be resorted to for the purpose of an exploratory myringotomy and the division of adhesions, the patient's consent for myringecto-ossiculectomy should be obtained, in case the condition revealed by exploration should render this advisable.

3. *Operations involving the Ossicular Chain.*—(*a*) *Excision of a portion of the manubrium mallei* and a large part of the membrana was proposed by Wreden [40] in cases where it was deemed desirable to maintain a permanent opening in the membrane. The procedure has fallen into disuse, and it is probable that it would not accomplish the end aimed at.

(*b*) *Disarticulation of the Incudo-stapedial Joint, or Division of the Long Arm of the Incus, with Mobilization of the Stapes.*—This measure is one of the most satisfactory operative procedures which fall to the lot of the otologist. It is of especial value when there has been previously a suppurative inflammation with destruction of the membrana tympani in the upper and posterior quadrant, or when the articulation is covered by a thin cicatrix only, through which the parts can be easily seen. It is of less value in cases of otitis media insidiosa, since the closure of the opening made for the performance of the operation renders it impossible for the surgeon to relieve by secondary operations any unfavorable results attending cicatrization.

In cases where both the long arm of the incus and the posterior crus of the stapes are in view and uncovered, the joint may be divided by inserting the angular knife (Fig. 1, *C*) behind the long arm of the incus and cutting downward through the joint; any portions of the capsule undivided may be severed by inserting the point of the knife into the joint below and cutting upward, and also by hooking the instrument around the anterior aspect of the long arm of the incus and cutting downward. It is usually advised that the knife be hooked around the posterior aspect of the long arm of the incus and the joint opened from above, downward and forward, the resistance offered by the stapedius muscle rendering this the simplest procedure for disarticulating at the joint. This is theoretically correct, but is open to several objections. In the first place, the long arm of the incus frequently lies so near the margin of the tympanic ring that the knife can only be inserted in this locality by the use of considerable force; again, if the joint is divided before section of the stapedius tendon has been done, the pull of the stapedius muscle may so displace the stapes as to render its subsequent mobilization impossible. My own method of procedure is therefore to thoroughly divide the stapedius tendon and the adjacent adhesions as the initial step of the operation. This is done in the manner already described, by inserting the sharp straight knife behind and above the head of the stapes, between it and the tympanic ring, carrying it inward until the point touches the inner tympanic wall and then cutting directly downward. By this procedure the stapes, and hence the articulation, is released, and by the action of the tensor tympani and the elasticity of cicatricial bands located anteriorly the articulation is brought more clearly into view. The anterior aspect of the descending crus of the incus is in such a position that by applying the angular knife to this, and cutting downward, the joint is easily divided, or it may be more convenient to enter the joint from below with the point of the knife, and cut upward, sweeping the blade anteriorly and posteriorly as a final step. If the knife is sharp no violence will be done, although the resistance afforded by the stapedius has been ablated.

After the joint has been divided the long arm of the incus is pushed upward and forward, so that it cannot reunite with the stapes. Attention is next given to the condition of the stapes, and if this is not freely movable it is to be freed by passing the pointed knife about the foot-plate, dividing all bands which may be found in the manner already described in treating of adhesions about the stapes. If the ossicle remains firmly fixed after these incisions have been made, it may be mobilized by pressing upon it with a cotton-tipped probe, the pressure being applied successively from below, from above, and upon the anterior and posterior crura. Care must be taken not to rupture the crura by this manipulation.

I have in quite a number of cases obtained a marked improvement in hearing and a diminution in the tinnitus by the division of the incudo-stapedial articulation and of the stapedius muscle, together with fibrous bands about the stapes, and this is, I believe, the experience of all otologists who have made use of the method. In a certain number of cases we find that the incudo-stapedial articulation has become ossified and division with the knife is impossible. In such an event Politzer [41] divides the long arm of the incus with stout scissors and separates the fragments so that reunion is impossible.

As before stated, mobilization of the stapes by division of the incudo-stapedial articulation and of adhesions about the ossicle is mostly of service in cases dependent upon a previous suppuration. In cases of otitis media insidiosa the mobilization of the stapes has been attempted, notably by Miot, [42] who enters the tympanum by an extensive incision along the posterior margin of the membrana tympani, and by means of a delicate instrument, the distal extremity of which is flattened into a small plate, mobilizes the stapes by pressure applied from below upward, from above downward, and upon the anterior crura backward. In certain cases also traction is made upon the long arm of the incus, to aid in the mobilization. The stapedius muscle and the incudo-stapedial articulation are left intact, unless the latter is ossified, when the long arm of the incus is divided. If adhesions exist between the incus, malleus, and the tympanic wall they are divided. The author claims that by frequent inflation by Valsalva's method the wound in the membrane can be kept open long enough to admit of several attempts at mobilization upon successive days, if the first does not afford the improvement hoped for. General anæsthesia is not considered necessary, as after the first incision through the membrane the introduction of a solution of cocaine into the tympanic cavity produces sufficient anæsthesia. In cases following a purulent inflammation the same general plan is followed, the author preferring to over-

come the rigidity by stretching the adhesions rather than by dividing them, although in certain cases he uses the knife. I have never attempted this method of procedure, but in one case of otitis media insidiosa I entered the tympanic cavity, and after dividing the incudo-stapedial articulation severed the stapedius muscle, as well as all adhesions about the base of the stapes. There was a moderate amount of reaction, and after the closure of the opening in the membrane the hearing remained the same as before operation, although the tinnitus was somewhat improved.

Although the method of Miot is certainly unique, and his results seem to have been good, yet I can scarcely believe that the operation will ever come into general use. There can, it seems to me, be no advantage in leaving in the tympanic cavity structures whose function has been so impaired by the inflammatory process that they are of little use, while by their presence they afford an additional opportunity for the recurrence of the condition for which operative measures have been instituted. Stretching of the adhesions may give temporary relief, but the method which, theoretically at least, would be the best, would be the one which prevented all possibility of their reformation. This indication, in my opinion, is better met by the free use of the knife, and the removal of all parts not absolutely necessary to the function of audition.

(*c*) *Plastic Operations for the Purpose of Uniting the Incus or Stapes with the Membrana Tympani.*—By means of the above procedure vibrations falling upon the membrana would be transmitted directly to the stapes; in cases, therefore, in which extensive adhesions existed, limiting the mobility of the malleus or incus, or both, or when, as the result of relaxation, the membrana tympani and one or both of the two larger ossicles by their own weight acted as a load to the conducting mechanism, this procedure, theoretically at least, should be beneficial. Blake[43] has performed operations of this character, but at present, in similar cases, he prefers stapedectomy. So far as I know, Dr. Blake has never published an account of these operations but refers to them incidentally in the above communication; he was also kind enough to explain the method to the writer three years since.

Operation.—A triangular flap from the posterior-superior quadrant of the membrane is turned aside, exposing the incudo-stapedial articulation; by means of the probe the mobility of the incus and stapes is determined; all tension due to adhesions about the stapes or to contraction of the stapedius muscle is relieved by incision. If, now, the incus and stapes move freely, the triangular flap is pressed against the long arm of the incus, and held in place by a pledget of cotton. If the incus is not freely movable, disarticulation at the stapedio-incudal articulation is performed, and the flap applied to the head of the stapes instead of to the long arm of the incus.

(*d*) *Removal of the Ossicular Chain in its Entirety or the Excision of Individual Ossicles.*—We come now to operations in which either the entire ossicular chain or individual ossicles are removed. These operations have either been done for the purpose of improving the hearing or relieving tinnitus, or, in cases where the function of the auditory apparatus was not sufficiently impaired to necessitate interference of any kind, they have been called into requisition for the arrest of long-continued suppuration which had resisted all other forms of treatment. It is evident at once that as one or all of these conditions may be present in any given case, it may often happen that the decision for or against operation becomes an exceedingly delicate matter. Given a case in which the hearing is good enough to allow the patient to carry on his vocation in life without the least annoyance, and yet with a chronic discharge from the ear, which has failed to yield to skilful treatment, we must be certain that any operative interference which may be advised for the cure of the otorrhœa will not impair the function of the organ. In another case, in which impairment of the hearing or severe tinnitus has resulted from a chronic non-suppurative inflammation of the tympanum, or has been produced by a previous suppurative process, the ear at the time advice is sought having been dry for a long period, no measures for relief can be strongly advised which may result in long-continued suppuration. The surgeon must, therefore, not only be able to hold out a fair prospect of success for the operation, in accomplishing the purpose for which it is to be performed, but must also be able to assert that no disagreeable consequences are likely to follow its performance.

The history of operations upon the ossicular chain is interesting, from the fact that it shows how the earlier operators hesitated to interfere with the parts intimately connected with the labyrinthine structures, and that it was only after a considerable period that it became a recognized fact that the labyrinth might remain uninjured in spite of considerable traumatism inflicted upon the ossicular chain, or even its complete loss.

As early as 1873 Schwartze[44] advised the removal of the malleus and incus for caries, but stated that removal of even a portion of the stapes should be avoided for fear of a purulent infection of the labyrinth. He also states[45] that as early as 1873 he practised removal of the malleus and membrana tympani and disarticulation of the incudo-stapedial articulation in cases of chronic non-suppurative inflammation. In this condition he apparently did not remove the incus, but simply disarticulated it from the stapes.

In 1876 Kessel,[46] having several years before proved that the removal of the columella in birds was not attended by severe consequences, effected mobilization of the stapes in a patient in whom the malleus and incus had been destroyed by suppuration. The operation consisted in tenotomy of the stapedius muscle, and the division of adhesions binding the foot-plate in the oval window. From the reading of this report there can be but little doubt that the membrane covering the oval window was punctured and a certain amount of perilymph allowed to escape. There was some improvement in the hearing and a diminution of the tinnitus, but more important than this, no severe symptoms followed. The same author,[47] at a later date, excised the membrana tympani, malleus, and incus, and mobilized the stapes in a case of complete closure of the Eustachian tube. While it had been demonstrated quite early that removal of the two larger ossicles was not a dangerous or difficult operation, but one which was frequently indicated in caries, and followed by good results, even when no suppuration had been present, yet it was not until several years later that these measures were practised to any extent. In 1885 Lucae[48] published an account of fifty-three operations in cases of sclerosis, and called attention to the necessity of excluding serious labyrinthine involvement by means of testing the hearing with a series of tuning-forks before holding out a hope of improvement from operative procedures. While Lucae's published results are not as favorable as might be wished, they certainly demonstrate the fact that in certain cases such operative procedures are in the highest degree beneficial, and warrant placing them among the legitimate means for improving otherwise hopeless cases.

In 1888 Sexton[49] reported a number of cases of chronic non-suppurative otitis media, in which excision of the membrana tympani, malleus, and incus had been beneficial.

The removal of the ossicles for the relief of chronic suppuration has been continually gaining ground, and thanks to the contributions of Kretschmann,[50] Stacke,[51] Ludewig,[52] Grunert,[53] and others, it is now looked upon as a recognized surgical procedure. All writers upon the subject of intra-tympanic operations, involving the removal of the ossicles, have until quite recently avoided interfering with the stapes, or at the most have recommended the division of adhesions about the ossicle, and subsequent mobilization by *brisement forcé*. Jack[54] and Blake[55] have, during the last year, demonstrated that the entire stapes may be removed without danger, and in many cases the result has been a decided improvement in the hearing. Both of these surgeons, as the outcome of experience, advocate the removal of the stapes for the improvement of the hearing in cases where the impair-

ment depends upon some lesion of the conducting mechanism, resulting from either suppurative or non-suppurative inflammation; the other ossicles are left *in situ*, unless carious. We have then to consider the following operative measures:

1. Removal of the malleus and incus.
2. Removal of the malleus, incus, and stapes.
3. Removal of the stapes (stapedectomy).

If the membrana tympani is present, this is also removed as completely as possible in performing the first two operations above enumerated, while in stapedectomy the membrane is left.

In cases where long-continued and uncontrollable suppuration exists, or is the sole cause for operative interference, the two larger ossicles will certainly require removal; the advisability of removing the stapes will depend upon conditions which will vary with the individual cases. If carious, the affected bone should certainly be removed; if healthy, the question of its removal will depend upon the condition of the hearing before the operation, and the probabilities of improving it by the excision of this ossicle, as indicated by the careful functional examination of the ear before the operation, and the amount of rigidity of the stapes, as determined by manipulation after the two larger ossicles have been removed.

When removal of any or all of the ossicles is to be practised for the improvement of the hearing,—the process which has given rise to the impairment having been either non-suppurative inflammation or a purulent inflammation which has ceased either spontaneously or as the result of treatment, leaving a rigidity of the conducting mechanism,—advice as to the propriety of operative interference is a matter of no little moment. In the first place the lesion must be located in the conducting apparatus by the tuning-fork tests already alluded to. It is not enough that the inspection of the ear reveals a pathological condition of the conducting mechanism. It must be proved that this is at present the cause of the defective audition, since secondary changes may have taken place in the labyrinth which place the case beyond all hope of improvement by any operation upon the conducting mechanism. Evidence of such involvement of the labyrinth can only be excluded by a careful functional examination, and the method which has served me the best purpose has already been given in the early part of this paper. Both Lucae and Kessel have called attention to the necessity of such an examination before undertaking operative interference for the purpose of improving audition, and the tests used by these observers are in the same line as those already described.

As to the choice of operation, much is to be said. In all the operative procedures previously described, the object has been to reduce weight or tension in the conducting apparatus, by the division of muscles, adhesions, ligaments, folds of the membrana tympani, etc., or to establish a communication with the middle ear by a permanent opening in the membrana tympani, thus admitting sound to the oval window more directly, this end being still further carried out, in certain cases, by disarticulation at the incudo-stapedial articulation. Each individual procedure has, in certain cases, been of undoubted benefit, and the lack of enthusiasm with which they have been viewed has been due to the fact that it has been impossible to declare positively that the rigidity was the result of a limited lesion, such as contraction of the tensor tympani, tension of the posterior fold or similar localized conditions, and experience has shown that the same pathological process which has caused any of these conditions, in the large majority of cases, has effected changes in other parts of the conducting apparatus as well, which would be uninfluenced by operations affecting one portion only of this mechanism. In other words, we can be pretty certain of rigidity of the conducting mechanism as a whole, but as yet cannot define the exact limits of the lesion. It seems rational, therefore, that removal of the membrana, malleus, and incus, by affording direct access of the sound waves to the oval window or head of the stapes, should meet the indication better, or that the evulsion of the stapes itself, by removing the effect of increased tension of the labyrinth caused by the binding down of the other structures within the tympanum, should be a rational method of procedure in cases demanding operative interference. When the two larger ossicula are excised, the operator usually endeavors to maintain a permanent opening into the tympanic cavity, while when the stapes alone is removed, this end is not aimed at; but if the membrana tympani is present every attempt should be made to restore it to its integrity after the operation.

While I do not favor criticism unsupported by personal experience, I cannot help feeling that the removal of the stapes alone, in cases where the membrana tympani is intact, the wound made by the operation being closed as quickly as possible, is not a commendable procedure. The two larger ossicles certainly perform no function, after removal of the stapes, while they certainly increase the probability of serious reaction following the procedure, since they aid in shutting off the atrium from the fornix tympani not only by their own presence but also by the preservation of the numerous folds of mucous membrane found in this region, which reduplications are obliterated by the removal of the two larger ossicula. Again, the presence of the membrana tympani itself must present a certain amount of obstruction to the entrance of waves of sound, while if the membrane, malleus, and incus are taken away, it will be possible, certainly in most if not all cases, to maintain a permanent opening into the tympanum. Still further, cases are met with in which complete anchylosis of the foot-plate of the stapes renders removal of the ossicle inadvisable or impossible, and the surgeon can only divide all adhesions about the foot-plate, in the hope of securing a slight amount of motion. In such an event it would certainly be of advantage to be able to divide, subsequently, any adhesions which might form during cicatrization, after the first operation. If the membrane and the two larger ossicles have been removed, access can be easily gained to the stapes without resort to general anæsthesia, even if the membrane has reformed, as the resulting cicatricial membrane is only slightly sensitive, and may be easily removed under local anæsthesia. More than this, by the obliteration of the folds of the mucous membrane lining the vault of the tympanum, no reaction follows repeated operative interference in these cases, and as these folds must, on account of their density, tend to reduce the amplitude of sonorous vibrations, their preservation cannot be urged for the purpose of improving the function of audition. The desirability of leaving the membrana tympani for the purpose of protecting the tympanum is not clearly proved, since the mucous lining of the middle ear, after exposure to the air for a short time, ceases to be sensitive, and secretes almost no fluid. If, however, the protecting influence of the membrana tympani is deemed important, this can be secured, even though the malleus and incus have been removed; for a large portion of the membrane may be left intact and made to adhere to the inner tympanic wall, thus affording a cutaneous covering, while at the same time access can be easily had to the oval window. That the operation of removing all of the ossicula is more prone to be followed by serious reaction than removal of the stapes alone, I am not prepared to admit. Certainly my experience has been that the reaction following the removal of the malleus and incus has been practically nothing. Stapedectomy, then, would be the operation of election in a case in which the stapes was easily accessible, but was bound so firmly by adhesions (due to a former otitis media purulenta) that disarticulation from the incus and the division of adhesions would produce no permanent effect, while at the same time the region of the stapes had been shut off from the other parts of the tympanic cavity by the previous inflammation. In such a case, removal of all of the ossicles would hardly be called for, while removal of the stapes would be simple, and the thin cicatrix would afford easy access to the region for the purpose of further operative procedures. In non-suppurative inflammation, if the portion of the drum membrane covering the stapes were very thin,

making it probable that, after removal of the ossicle, the flap of the membrane would fall inward and adhere to the tissues over the oval window, thus affording no barrier to the entrance of sound, here again stapedectomy might be chosen; it is also applicable to certain cases in which, for any reason, general anæsthesia is objectionable, the patient possessing sufficient self-control to permit of the operation being done under local anæsthesia. As before stated, the membrana tympani is often partially or completely anæsthetic, and, after an opening has been made into the middle ear, perfect local anæsthesia can be obtained by the introduction of a ten per cent. solution of cocaine. Much will here depend upon the command which the patient has over himself, and the operator is certainly working at a disadvantage, but special circumstances may make the trial advisable, the possibility of failure having been explained to the patient before the attempt is made. In all other cases, however, I believe it is much simpler to clear away the other structures first, and then to decide whether the stapes should be removed or left *in situ*.

The technique for the removal of the membrana tympani, malleus, and incus is the same whether the stapes is to be removed or left in position; hence, to describe both operations separately, would be but a repetition. I shall give, therefore, the steps for the removal of all the ossicula, the reader understanding that, in case the stapes is to remain, the steps to be carried out up to this point are exactly the same. The method of operating differs somewhat, in cases where the membrana tympani is intact, from that employed when it is partially or almost completely destroyed, and the technique in each will be given.

Technique of the Removal of the Membrana Tympani and the Ossicles when the Membrana Tympani is Intact.—With the sharp knife (Fig. 156, *F*) an incision is made through the membrana tympani in the upper and posterior quadrant, commencing just below the point where the posterior fold meets the tympanic ring, and, following this curve, is carried downward to about the middle of the posterior border of the ring. This incision is made close to the insertion of the membrana, but should lie entirely in the clear membrane, for the reason that if this is done no hemorrhage results. For the same reason care must be taken not to wound the inner wall of the tympanum with the point of the knife, as any bleeding greatly obscures the field of operation, and renders the succeeding steps more difficult. The edges of the incision are now separated, and the incudo-stapedial articulation is usually clearly and easily exposed. If sufficient space is not gained, a horizontal incision may be made from the upper extremity of the first, forward toward the short process of the malleus, the section following the course of the posterior fold, and lying just below it, thus avoiding the more vascular tissues. In this way a flap is formed, which, on being turned downward, enables the operator to see the incudo-stapedial articulation clearly. The next step is the division of the stapedius tendon; this may sometimes be seen, running from the neck of the stapes backward, disappearing behind the tympanic ring; frequently, however, the head of the stapes lies so close to this structure that the tendon cannot be seen; in such a case the pointed knife used in dividing the membrana tympani is inserted close to the head of the stapes, and slightly above it, and carried inward until the inner wall of the tympanum is reached; a short cut downward is then made, carrying the knife between the head of the stapes and the tympanic ring, while the point is still firmly pressed upon the inner wall of the tympanum. In this way the muscle is thoroughly divided. When the tendon can be seen, its division is perhaps more simple, but in either instance the point of the knife should be firmly pressed against the inner wall of the tympanum, in order that the tendon and any adhesions about it may be thoroughly and completely severed.

As soon as this has been done, the action of the tensor tympani will bring the incudo-stapedial articulation and the stapes more clearly into view. The next step is the division of the incudo-stapedial articulation, which is effected with the angular knife (Fig. 156, *C*). The knife, inserted into the handle in such a way that the point is directed backward, is carried into the tympanic cavity in front of the long arm of the incus, and the blade passed to the inner side of this process; by slight traction outward and pressure backward the instrument is made to hug the descending process of the incus, while, at the same time, the articulation is divided with a downward stroke. Any fibres of the capsular ligament which may have escaped division may be severed by inserting the point of the knife into the articulation from below, and sweeping the blade backward and forward. If fibres still remain undivided posteriorly, the angular knife is to be turned in an opposite direction, the point directed forward, when by passing it behind the long process of the incus, a downward stroke will complete the division.

If these steps have been carried out as indicated, it will be the exception if more than a drop of blood has been lost.

Next, with the pointed knife, a short, horizontal incision is made through the membrana tympani at its most dependent part, close to the insertion into the annulus tympanicus; the pointed knife is quickly laid aside and the probe-pointed knife (Fig. 156, *E*) is inserted, and the membrane is divided along its posterior periphery from below upward, until the exploratory incision is encountered. In the same manner the anterior segment of the membrane is divided from below upward with the probe-pointed knife, the incision extending as far as, but not into, Shrapnell's membrane. Up to this point no blood has been lost and the field of operation is as clear as when we started. There remains to be divided the membrana flaccida and the ligaments which bind the malleus externally, in front, and behind. The pointed knife is again used for this section, which should be made rapidly; the knife is held so that the flat surface of the blade looks toward the roof of the canal, the cutting edge being directed backward; the point of the knife is entered just above the short process of the malleus and is pushed inward and upward, the handle being depressed so that the shaft often touches the margin of the speculum. In this manner the knife is made to enter the fornix tympani; it is now made to cut its way out, downward and backward, thus severing the external and posterior ligaments of the malleus and dividing the membrana flaccida posteriorly. The knife is then quickly turned and made to cut in the opposite direction, being carried forward over the short process, dividing the anterior segment of the membrana flaccida, some fibres of the external ligament, and the strong anterior ligament of the malleus. The malleus is now held only by the superior ligament and the tendon of the tensor tympani, neither of which is strong. The hemorrhage from the last incision may be free, and may obscure the field, but, usually, owing to the elevated position of the head, the upper part of the field is not obscured, and the short process of the malleus can be distinctly seen. The ossicle is quickly grasped, just below the short process, with the forceps (Fig. 157), and by pressure inward to dislodge the neck of the bone from the projection on which it rests, followed by traction downward and then outward, the ossicle is extracted; no force is required to rupture the tendon of the tensor tympani or the superior ligament, as they offer very little resistance.

It will be necessary now to wipe out the blood which has followed the removal of the malleus, but in most cases a single pledget of cotton will dry the cavity completely. The incus is next sought for, and, if in sight, is grasped with the forceps and removed, traction being exerted at first downward and then outward. Most frequently when the incus is in view, the long process will be seen, not in the normal location but lower down, and lying close to the border of the tympanic ring, so close, frequently, that it is easily overlooked, apparently constituting a part of the ring. Manipulation by means of a probe reveals its identity, and the ossicle can be extracted in the manner already described. This displacement of the incus downward and backward is due to the fact that in the removal of the malleus the capsu-

lar ligament binding the two ossicles together must be ruptured. The incus itself is attached to the tympanic wall simply by means of a single ligament running from the short process of the incus to the wall of the fornix tympani. Traction downward on the malleus displaces the incus downward and also revolves it backward, the short process being the fixed point. Thus, frequently, after the malleus has been removed, careful inspection of the field of operation fails to reveal any trace of the incus, it having been rotated entirely out of sight behind the tympanic ring. To effect its extraction is not always easy, and yet in cases where there has been no suppuration it will rarely happen that the ossicle will escape. When not in sight, the long process of the incus can be easily brought into view by means of the incus hooks (Fig. 156, *H*). These hooks are curved in opposite directions for the right and left ear, the concavity of the curve looking anteriorly in each case when the instrument is inserted into the handle with its angular extremity directed upward. The incus hook is passed into the tympanic cavity, and the angular portion passed behind the tympanic ring close to the floor of the canal, the hook being inserted in such a way that the concavity of the hook looks upward. When the angular portion of the instrument has entirely disappeared behind the ring, the instrument is drawn outward until it is felt to press closely upon the inner surface of the tympanic ring, when it is rotated forward, at the same time being carried a little upward. Usually this manipulation swings the long arm of the incus into view. The difficulty sometimes met with in securing the incus usually lies in the fact that the operator is inclined to search for the ossicle too high up in the tympanum and to forget that the long process lies close to the margin of the ring; the hook is, therefore, frequently carried too deeply into the tympanic cavity and fails to engage the long process. This manœuvre is to be repeated several times in case the first effort is not successful. If no free body is felt with the hook posteriorly, it is then inserted into the tympanum, at the anterior inferior portion, with the curve of the hook directed posteriorly; the hook is now rotated, sweeping the extremity which hugs the tympanic ring closely, backward, and at the same time carrying the instrument somewhat upward. This manipulation will bring the incus into view in case the posterior ligament of the incus was ruptured during the removal of the malleus, allowing the ossicle to fall into the lower part of the tympanic cavity, an event which may sometimes happen.

If the ossicle is not found in either of these situations the hook should be swept upward and forward through the postero-superior and superior portions of the tympanic cavity, keeping it still pressed firmly against the internal margin of the ring. Care is to be taken in this manipulation that the hook does not pass between the crura of the stapes or fracture them as it is carried forward. If the ossicle still remains hidden, the hook having the opposite curve should now be used, being carried into the fornix tympani, with the concavity directed backward, the angular portion of the instrument being hooked behind the inner extremity of the superior wall of the meatus; the instrument is now rotated backward, and at the same time is carried downward, rotation being continued through an angle of 180°. The object of this manipulation is to dislodge the incus, in cases where its posterior ligament is very strong, or where the long process has been rotated far backward out of reach of the hook. After this downward sweep it is well to repeat all of the steps for dislodging the incus in the order named, as this last manipulation may displace the ossicle downward, although it may still remain hidden from view. The objection to beginning the search in the manner last mentioned lies in the fact that if the ossicle is already free, or nearly so, the manipulation is apt to displace it so far toward the mastoid antrum as to render it entirely inaccessible. I have written upon the method of extracting this ossicle somewhat at length, because I believe it to be extremely important to remove it if this be possible, and I feel certain that the advantages gained in its extraction are more than enough to warrant prolonging the operation for this purpose.

After the incus has been removed the cavity is thoroughly dried, and the region of the round window inspected. Any thickening in this situation should be overcome by cutting away the hypertrophied tissue, if present in sufficient amount to permit of this. Usually, however, we find simply a thickening of the mucous membrane about the fenestra. Stellate incision of this thickened tissue, by means of the angular knife (Fig. 156, *B*), most frequently relieves the tension.

The stapes is next inspected and its mobility tested. If rigid, all adhesions about it should be divided; if its motion is now free, the operation may be considered completed. If, on the other hand, the motion of the stapes is still impeded, or if the adhesions have been found so extensive that, after these have been divided, cicatrization will probably render the ossicle rigid again, the stapes should be removed. All soft tissues binding it down should be carefully severed with the sharp knife passed around the foot-plate, after which a delicate hook is passed between the crura and the ossicle is removed by traction. It is often more easy to grasp the head of the bone with the forceps, and remove it in this way than by making use of the hook.

In cases where difficulty is experienced in finding the incus, and it is deemed necessary to remove the stapes, this ossicle being easily seen, it is often wise not to delay the removal of the stapes until the incus is found, since in the manipulations necessary to displace the incus the crura of the stapes might be accidentally broken, or the head of the bone be so displaced as not to be easily seen. Hence, if the incus is not readily found, the stapes may be removed as the second step of the operation, and the incus subsequently searched for. If the stapes is removed at this stage of the procedure, care must be taken in searching for the incus that the incus hook is not passed through the oval window, thus injuring the labyrinth. This may seem a needless precaution, but any one who has studied the parts upon the cadaver will appreciate how easily the incus hook could be passed through the thin membrane covering the fenestra ovalis. The reason of this lies in the fact that the plane of the oval window is not vertical, but inclined downward and outward. When this opening is situated high up, and is almost hidden by the tympanic ring, the incus hook may be easily carried under its upper margin and through the membrane covering the opening, the operator mistaking the resistance offered for that of the tympanic ring. If the posterior wall of the canal is closely followed, and the incus hook made to enter the tympanum low down, and it is made afterward to hug the tympanic ring closely, this accident cannot occur.

In some instances the margin of the tympanic ring hides the stapes so completely that this ossicle can hardly be seen, and it is impossible to form an intelligent opinion as to its condition, or to effect its removal. In such an event the margins of the ring in this situation may be cut away by means of the forceps shown in Fig. 159. These forceps are so constructed that when open the distal extremity of the lower blade can be passed up behind the tympanic ring. Upon closing the instrument the chisel blade cuts away a small chip from the overhanging wall. By repeating this procedure, enough space can be gained to permit of access to the stapes and oval window.

Occasionally the foot-plate of the stapes will be found to be so firmly fixed in the oval window that it cannot be loosened, and that after dividing all adhesions its removal is impossible, the crura sometimes being broken in the attempt at extraction. In such an event the operator should proceed with the greatest caution. All the soft tissues should be carefully removed from the oval niche by means of the short angular knife (Fig. 156, *B*) and a delicate curette. If the outline of the foot-plate can now be made out, a pointed knife should be carried around its periphery, in the hope of making an opening at some point where the union is less firm; through such

an opening a delicate hook can be introduced and a part at least of the foot-plate brought away. If complete ossification has taken place, I should advise the cautious use of a small guarded drill, which might be made to perforate the foot-plate at its centre, after which portions might be removed with the hook. I have never had occasion to do this upon the living subject, but should not hesitate to do so, using, of course, great care; it would be possible to carry out this step without evacuating the perilymph, but even if a small quantity of the fluid should be lost, Kessel's [66] observations have proved that no harm results.

After all the operative steps deemed necessary have been carried out, the cavity is to be dried with pledgets of cotton, and a tampon of iodoform gauze introduced. This is packed rather firmly into the tympanum, while the canal is but loosely filled. The object of the gauze is to check any oozing which may occur, and prevent the formation of a blood-clot within the middle ear, for if this is allowed to form it may give rise to considerable pain, by preventing the escape of secretion during the first days after the operation, at which time its removal is apt to be somewhat painful. A few hours after the operation, this tampon is removed, and the ear douched with a warm weak antiseptic solution, such as a saturated solution of boric acid, or a solution of bichloride of mercury, 1 to 8,000, after which the tampon is reinserted. When the odor of iodoform is objectionable, sterilized or borated gauze

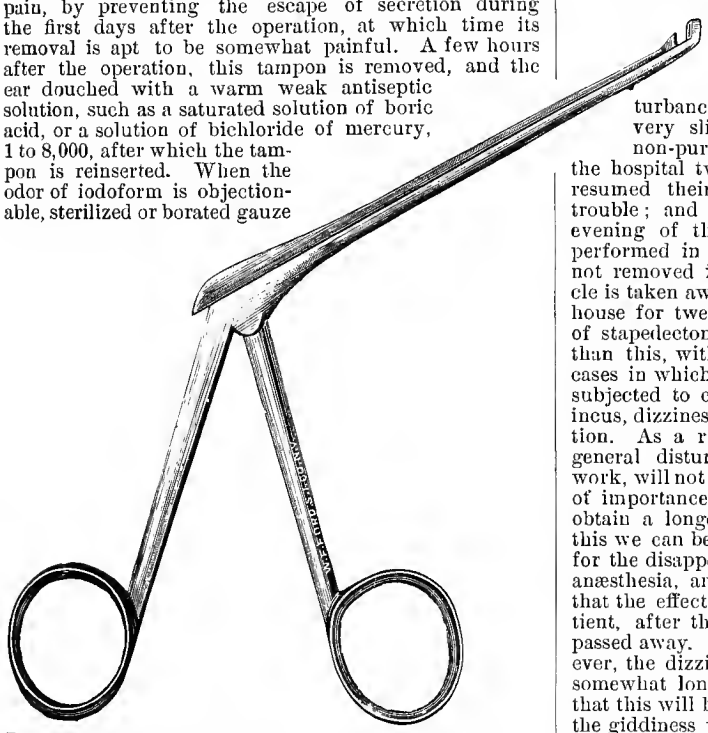

Fig. 159.—Cutting Forceps for the Removal of a Portion of the Inner Extremity of the External Auditory Canal.

may be used. This second tampon is allowed to remain for from twelve to twenty-four hours. The subsequent treatment depends upon the amount of local reaction following the procedure. If there is but little discharge, the cleansing of the ear once daily by the surgeon, followed by the insufflation of boric acid, dermatol, or some kindred powder, will be all that is necessary. If the patient cannot be seen daily, as is usually the case in dispensary practice, gentle syringing of the ear once or twice daily, according to the amount of discharge, is all that will be required, and I have never thought it wise to trust the insufflation of any powder to the patient. When the discharge is only slight, even the syringing is objectionable, and an intelligent patient may be allowed to cleanse the ear, by simply wiping it out with a pledget of cotton wound upon an appropriate cotton-holder. On the other hand, if at the end of a week there is still considerable secretion, the patient is directed to instil a few drops of a solution of boric acid in alcohol, of a strength of twenty grains to the ounce, after each syringing. The amount of discharge after the operation will depend upon the habit of the patient, and also upon the condition of the mucous membrane of the tympanum. In cases of advanced sclerosis, the amount is frequently insignificant, especially if the patient is not of a full habit. On the other hand, when the tympanic cavity or the fornix tympani has been full of connective tissue rich in blood-vessels, the discharge following the operation will be more profuse. It is probable, also, that prolonged manipulation within the cavity at the time of the operation, favors a more profuse discharge, although this is certainly not so in all cases, and should not deter the operator from doing a deliberate and thorough operation.

I have written somewhat at length about the management of the cases after operation, because I consider this an important point. In a general way, the less that is done after the operation, the more likely we are to obtain a permanent opening into the tympanic cavity, a condition always to be desired. Hence, the aim should be to keep the ear clean with as little manipulation as possible, and to avoid the use of astringents or caustics to stop the discharge, since they will certainly promote the reformation of the tympanic membrane.

With reference to the amount of disturbance caused by the above procedure, this is very slight. In forty cases, both purulent and non-purulent, all, with the exception of five, left the hospital twenty-four hours after the operation, and resumed their regular daily work without the least trouble; and quite a number returned home upon the evening of the same day, the operation having been performed in the afternoon. Of course the stapes was not removed in all of these cases, and when the ossicle is taken away, I prefer to confine the patients to the house for twenty-four hours at least; yet in three cases of stapedectomy the patients returned home in less time than this, without any unpleasant effects, while in two cases in which this ossicle was left *in situ*, but had been subjected to considerable manipulation in securing the incus, dizziness persisted for several days after the operation. As a rule, the patient can be assured that any general disturbance, sufficient to incapacitate him for work, will not last more than twenty-four hours, an item of importance among those who find it impossible to obtain a longer respite from their daily vocation. Of this we can be as certain as in allotting the same period for the disappearance of the unpleasant effect of general anæsthesia, and the surgeon is justified in promising that the effects of the operation will not detain the patient, after the disturbance due to the anæsthetic has passed away. When the stapes is to be removed, however, the dizziness may make locomotion difficult for a somewhat longer period, and if there is a probability that this will be necessary, it is not wise to promise that the giddiness will not interfere with locomotion for several days, although in quite as many cases the reverse has been true. If the malleus and incus alone are removed it will be decidedly rare for any such disturbance to follow.

Pain or severe local inflammation I have never met with as the result of these operations, for the reason, I believe, that such perfect drainage exists that no retention of secretion is possible. In this respect I feel certain that the complete removal of the ossicles and membrane commends itself, when compared with some of the intratympanic operations, in which less apparent violence is done, but in which free drainage is not secured.

As regards the partial or complete reproduction of the membrana tympani, my experience has been that, as a rule, the membrane will reform, although this is not always the case. For dealing with this result the removal of the two larger ossicles is of great advantage. The membrane which reforms is usually thin, and not as sensitive as the normal membrane, and its removal is but a trivial matter, both for the patient and surgeon. Again, its reproduction does not always impair the result of the operation. In cases, however, in which, after the membrane has been reproduced, the hearing becomes

worse than while a perforation was present, it should be removed. General anæsthesia, in my experience, has never been necessary; a pledget of cotton smeared with a ten per cent. ointment of cocaine in lanolin, renders the membrane sufficiently anæsthetic for incision; after which a drop of a ten per cent. aqueous solution of cocaine, introduced into the tympanic cavity, renders the remainder of the operation painless. The operation is best performed by passing the straight knife (Fig. 156, *F*) through the membrane close to the tympanic ring and just above the head of the stapes, and dividing the posterior attachment of the membrane close to the ring for a short distance, great care being taken not to wound the mucous membrane of the tympanum. The probe-pointed knife should then be substituted, and the attachment followed downward to its lowest point. It will then be found that the tissue is so relaxed that division of the anterior attachment is difficult; to overcome this, the sharp knife is again passed through the membrane at its upper part, just in front of the original puncture. A little pain is usually experienced from the incision, but it is only momentary. The anterior attachment is now divided downward with the blunt knife, until the incision meets that which severed the posterior attachment. Usually the relaxation interferes with the complete section. The membrane is now held by a thin strip of tissue above and below. A touch with the sharp knife severs these attachments, or weakens them to such an extent that the entire membrane can be easily removed with the forceps. The procedure is so simple that if attention is given to the aseptic condition of instruments and field of operation, no reaction results. The operation may be performed safely at the office of the physician, and the patient at once allowed to resume his usual duties. It is well to protect the ear by the insertion of a cotton pledget, which need not be worn for more than twenty-four hours after the removal of the new membrane. The patient should be cautioned to guard against taking cold, but, further than this, no special precautions are necessary. The procedure is not likely to be followed by any discharge, and all syringing of the ear is to be avoided, unless pain or profuse discharge supervene, as disturbing the parts in any way may excite enough reaction to cause a reproduction of the membrane.

One point is worthy of special attention, and that is, that the removal of a membrane which has formed after operation should not be undertaken until all traces of inflammation have disappeared. The surgeon must wait until the newly formed tissue is pearly white and glistening, and until the mucous lining of the tympanum has also assumed its normal condition, as evidenced by the absence of redness, engorgement of its vessels being easily made out through the thin cicatricial membrane. If this rule is not observed the operation will be more painful, and reproduction is almost certain. If the membrane reform again, a second or third removal is still more simple, as the density of the tissue is less each time that it is reproduced. In one case this was so marked that after the first incision the edges of the wound retracted so widely that it was possible to remove only a minute portion of the new-formed tissue, and yet the tympanum was freely exposed, and no reproduction has followed at the end of several months.

In plethoric individuals a persistent reproduction of the membrana tympani after excision can be prevented by a restriction of the diet for a few weeks previous to and following the secondary removal of the structure. This is suggested by Sexton,* and I have proved its efficacy.

In certain instances it may be found that the new membrane has become adherent to the inner wall of the tympanum, thus rendering its complete removal difficult. In one such case, in which the stapes had been left *in situ*, the hearing remaining impaired, apparently on account of the stapes being bound down by the newly formed membrane, this structure was divided first behind the head of the stapes and the incision carried downward close to the tympanic ring for a distance equal to about one-third its posterior margin. The stapes then lay free while in front there was a flap, attached by adhesions to the inner tympanic wall; this flap was turned forward and the underlying wall of the tympanum was scarified, after which the flap was replaced and pushed down upon the wall of the middle ear, care being taken that the free margin lay below the tympanic ring. Adhesion at once resulted, leaving the stapes projecting into the canal, while the tympanic cavity was largely obliterated from the adhesion of the membrana to its inner wall. Thus the middle ear was thoroughly protected by a cutaneous covering, while the parts essential to audition remained accessible for further operative procedure. The patient, though better, is still under treatment, and I hope for still further improvement following the division of remaining bands which bind the stapes. It may be advisable in certain cases to preserve the anterior portion of the membrana tympani in removing the malleus and incus, and, after scarification of the inner wall of the tympanum, to attempt to secure adhesion of the anterior segment of the membrana to this. In this manner we might shut off the anterior part of the tympanic cavity from the posterior portion, which contains the structures concerned in audition. The posterior portion would in this manner become covered by epithelium from the surface of the membrana tympani, and the objection of having an exposed mucous surface would be avoided. In this manner we could by care secure a thin epithelial covering for the round and oval windows, the stapes being removed, or not, according to indications. I have never performed the operation with this object in view, but from the fact that nature occasionally succeeds in doing this unaided, it may not be out of place to suggest it here as worthy of trial.

Technique of Operation where the Membrane is Partially or Almost Completely Destroyed.—When a purulent inflammation has resulted in the destruction of a considerable portion of the membrana tympani, the method of procedure must be to a certain extent modified. In some of these cases we shall find the lower portion of the membrana wanting, the membrana flaccida thickened and highly vascular, binding the ossicles down and concealing them more or less completely; we may be able to recognize by inspection only the prominent short process of the malleus and a portion of the manubrium, the latter lying almost horizontal, its tip bound firmly to the upper part of the inner tympanic wall. Behind the short process examination with the probe reveals the incus and stapes as present, but whether in their entirety or not cannot be determined. In other cases, while there may have been extensive destruction of the membrana tympani, the posterior superior segment is covered with a thin cicatricial membrane through which the incudo-stapedial articulation is plainly seen, or this joint may be completely exposed, no covering being present. My rule has been in all cases where the incudo-stapedial articulation is visible, or where this region is covered by a non-vascular membrane whose division will not lead to annoying hemorrhage, to first divide the stapedius muscle and then the incudo-stapedial articulation, in the manner described when considering the method of operation in cases in which the membrana tympani is intact. When, however, it is evident that an incision in this region will be followed by hemorrhage, such a step only serves to complicate the operation, as the bleeding will render it impossible to see the incudo-stapedial articulation and divide it with certainty, and will frequently completely obscure the field of operation and hide even that most prominent and important landmark, the short process of the malleus, and considerable difficulty may be experienced in removing this ossicle even. Experience shows us that when this condition exists there is very little hemorrhage after the membrana flaccida has been completely freed from its attachments and removed, together with the malleus. Our first step, then, must be to insert the straight pointed knife above the short process, pushing it inward and

* The Ear and Its Diseases, New York, 1889, p. 392.

Ear Operations.

upward until the inner wall of the tympanum is encountered, where it is made to divide rapidly the attachments of the remnant of membrane to the tympanic ring by directing its edge backward and incising close to the margin of the ring, and then, without removing it from the wound, to turn the edge in the opposite direction and divide the anterior attachments. In cutting backward the operator must bear in mind that the incudo-stapedial articulation has not been severed, and in this region as little force as possible should be used; for this reason also the posterior incision should be first made as above directed. Almost immediately the fundus of the canal fills with blood, but for a few seconds at least the short process is plainly visible, and if examination has shown us that the manubrium is not firmly bound to the promontory, the malleus is at once seized with the forceps just below the short process and removed in the manner already described. If, however, firm adhesions are known to exist, or if the malleus is found to be firmly fixed upon grasping it with the forceps, no force should be used to effect its removal, but the canal should at once be tamponed firmly with cotton by carrying an elongated plug to the tympanic cavity with the forceps and pressing it firmly upon the tympanic wall, the remainder of the plug being then forced inward. Upon this tampon a second and third are crowded until there is no bleeding about the plugs. If held in position for a few moments and then removed with the forceps, the field of operation will be found to be dry, the bleeding having been entirely checked. Any given area can be more completely cleansed by touching it with a small pledget wound upon a cotton-holder. The adhesions binding the malleus to the promontory can now be divided with the blunt knife curved on the flat (Fig. 156, *D*), after which the ossicle is removed by means of the forceps. If the malleus is still firmly fixed, manipulation by means of the probe will determine the situation of the undivided attachments, and their section can be effected.

When it has been possible to divide the incudo-stapedial articulation as the initial step, I frequently remove the malleus in the manner above described as the second step of the operation, in place of first freeing the remnant of the membrane from its peripheral attachments below, anteriorly, and posteriorly; this, of course, applies to cases in which the greater portion of the tympanic membrane has been destroyed. When only a comparatively small portion of the membrana vibrans is wanting and excision is deemed proper, it may be well, after dividing the incudo-stapedial articulation, to sever the peripheral attachments of the membrane from below upward, by means of a blunt knife introduced through the perforation. As a rule, however, so many adhesions exist between the inner tympanic wall and the lower portion of the membrana that such a procedure is unadvisable; moreover, the parts are frequently so vascular that the attendant bleeding may complicate the more important part of the procedure—the division of the superior attachments and the removal of the malleus. It is usually wiser, in these cases, to divide the upper segment first, the knife being carried into the perforation in terminating the posterior and anterior incisions.

It may seem hazardous to subject the stapes to the possibilities of violence attendant upon removal of the malleus before the incudo-stapedial articulation has been divided. A moment's reflection will convince one, however, that the increased formation of connective tissue which renders the procedure necessary also fixes the stapes so firmly that intelligent manipulation can scarcely displace it, while the danger of inflicting such an injury is much greater if an attempt is made to divide the articulation with the field of operation partially obscured by blood. Again, it frequently happens that the long process of the incus has become necrotic, and the articulation destroyed, so that no connection between the two ossicula exists.

After the malleus has been removed, the stapedius muscle and incudo-stapedial articulation should be sought for and divided, unless this step has already been performed, after which the incus is sought for in the manner already fully described. It should be remembered that as caries more frequently attacks the incus than any other ossicle, it may be partially or completely destroyed. In the former case its removal is often difficult, while it is important to determine with certainty the latter condition, to avoid overlooking it if present, or a prolonged search if it is absent. It should also be borne in mind that the pathological process may have resulted in a bony union between the incus and malleus, and that both ossicles may be extracted together. In case both ossicles were intact, the operator could not overlook such an occurrence, but when one or both have been partially destroyed, careful inspection of the portions removed may be necessary, to determine simultaneous removal of the malleus and incus. The operator should then, upon extracting what he supposes to be the malleus, carefully examine it, in order to assure himself that the body of the incus is not attached thereto. If nothing but the malleus is found, the field of operation should be dried and inspected carefully. If no portion of the ossicle is seen, special attention should next be given to the posterior-superior segment of the field. It sometimes happens that the incision has not been close to the tympanic ring in this region, a circumstance not easily recognized unless the parts are touched with the probe, when it will be found that a small curtain, or flap, of tissue remains undivided. A destruction of a small part of the ring at this point, as the result of caries, also gives rise to a similar appearance. It quite frequently happens that the incus is adherent to this flap, or completely concealed by it; division of the soft parts close to the bony margin will, in such a case, bring the incus into view. If not found in this situation, the ossicle must be searched for with the incus-hook, in the manner already described while considering cases with intact membrana tympani. If all of these manipulations fail to bring the incus into view, or if it has not been felt, and the incus-hook can be carried freely, from behind forward, through the vault of the tympanum, the operator may decide that the ossicle has been destroyed by caries, or that it has suffered partial destruction, and the remaining portion has become amalgamated with the tympanic roof. If, however, it has been seen or felt at any time, its subsequent loss will mean dislocation into the mastoid antrum.

The management of the stapes and the region of the round window is conducted in the manner already described.

Any parts of the membrana tympani which may remain in the lower portion of the fundus are to be removed with the knife and forceps if they are the seat of an hypertrophic process, as evidenced by considerable thickening and increased vascularity, as they may conceal areas of bony necrosis. If, however, the appearance of the lower portion of the membrane is healthy, we may feel certain that the bony structures are unaffected, and that there is no indication for the removal of the lower portion of the membrane; in fact, its presence will hasten cicatrization.

After drying the tympanum thoroughly we should next search for softened bone, both by inspection, which will often reveal here and there unhealthy granulation tissue indicative of the presence of dead bone, and with the probe, which should be made to explore thoroughly the entire inner wall of the tympanum, and should also be bent at a right angle at the tip, to enable the surgeon to thoroughly explore the tympanic vault. The curette should then be freely used, and all granulation tissue and softened bone should be removed. For the atrium, the straight curette (Fig. 156, *A*) will be found serviceable, but for the vault the sharp spoons, bent at a right angle (Fig. 156, *G*), must be called into requisition. This procedure of thoroughly removing and curetting the entire cavity is of the greatest importance, and should be conducted with special care, as the ultimate success of the operation often depends quite as much upon this step as upon the removal of the ossicles. An area of softened bone in the vault of the tympanum will keep up the discharge for a long time, and render the result of the opera-

tion far from satisfactory. Hence quite as much attention should be given to this procedure as to the removal of the ossicula. After the bony walls of the tympanum have been thoroughly curetted, the margins of the tympanic ring should receive attention. It frequently happens, when long-continued suppuration has existed, that the margin of the ring becomes involved. This is particularly true of the superior and postero-superior margin, on account of its intimate relation to the ossicula, and because it is the floor of a portion of the vault of the tympanum. Any roughness or softening in this region should be dealt with in the same manner as in the case of a similar condition in other portions of the tympanum ; all diseased areas should be removed with the curette, and a portion of the margin may be excised with the cutting forceps if necessary.

After all these steps have been carried out, the treatment of the case for the first few days does not differ from the after-treatment of cases in which the membrana tympani was originally intact. The subsequent treatment, however, must vary with each individual case. While the discharge continues profuse, the ear must be cleansed with the syringe and mild antiseptic solution in the hands of the patient twice daily, or more frequently if this is necessary to keep the parts clean. At the end of a week, if there is considerable discharge, I recommend the instillation of the solution of boric acid in alcohol twice daily, after thorough cleansing. Any granulation tissue must be destroyed as it appears, by means of chromic acid, silver nitrate, the actual cautery, or any other destructive agent. If it is found that all carious bone has not been removed, lactic acid, applied by means of a cotton-tipped probe to the affected areas, is frequently sufficient to determine the formation of healthy granulation tissue, and effect complete cicatrization. The concentrated acid should be used, and should be thoroughly rubbed into the tissues. As the discharge becomes almost *nil*, the syringe may be dispensed with, and the patient allowed to cleanse the ear by means of pledgets of cotton wound upon any convenient probe, while the surgeon may once or twice weekly insufflate a small quantity of boric acid, dermatol, or other mild antiseptic or stimulating powders, until all discharge ceases. It has been my good fortune, in all such cases, to either stop the discharge completely or to diminish it so much that it has ceased to be a source of annoyance. The length of time which must elapse after the operation, before the discharge will completely cease, must vary with each case, depending upon the extent of the original involvement. In general, from six to eight weeks will probably be the average time ; in some cases cicatrization may be perfect at the end of two or three weeks, while in others the same number of months must elapse.

The technique given above varies in some particulars from that advocated by other operators.

In the division of the incudo-stapedial articulation the ordinary direction is to enter the knife behind the long arm of the incus and divide the articulation by cutting downward and forward. Those who advocate this plan of procedure say that the pressure of the instrument is then opposed by the action of the stapedius muscle, and danger of injury to the stapes is avoided, while at the same time the resistance of the stapedius renders the division more easy. My own preference is to completely sever the stapedius tendon before attempting to disarticulate, as by this means the articulation is brought more perfectly into view by the action of the tensor tympani and tense ligamentous bands located anteriorly. If the stapedius muscle is not completely divided as the initial step, the stapes, after disarticulation, is frequently pulled out of sight behind the margin of the tympanic ring. After division of the stapedius, disarticulation by the above method may dislocate the stapes, although this is not likely to occur. It is often difficult, however, to insert the knife between the tympanic ring and the long arm of the incus, and for this reason I prefer the method given in my description of the technique of the procedure—that is, to pass the angular knife in front of the long arm of the incus, and open the articulation by cutting downward and backward against the pull of the tensor tympani ; or to open the joint at its lower aspect, and then to sweep the knife through it by carrying it backward and forward. By either of these methods the joint is more easily opened than when an attempt is made to carry the angular blade behind the long process of the incus, which frequently lies so close to the tympanic margin that considerable violence must be used in introducing the knife.

In removing the incus Kretschmann,[57] who was the first to formulate the procedure for removing this ossicle, made use of a hook which, in addition to the curve shown in Fig. 156, *H*, was bent outward at the distal extremity, so that when the instrument was in position, the tip rested upon that small shelf-like structure of the superior wall of the canal which affords lodgement for the incus. He introduced the instrument with the concavity directed backward and brought the incus into view by rotation backward and traction downward. While this manipulation is no doubt of great value in certain cases, the backward rotation seems more likely to carry the ossicle far out of reach toward the mastoid antrum, in case it is not secured at once, and the manipulation of attempting to bring the long process into view by passing a hook behind it and rotating forward, has in my hands proved very satisfactory, while it certainly lessens the danger of displacing the ossicle far backward.

The teaching that it is not advisable to make a prolonged search for the incus, seems to me to be unwise. In non-suppurative cases careful manipulation will render failure to secure it exceedingly rare. If it has not been displaced, it must occupy its original position, and failure to bring the long process into the field of vision will render it impossible for the operator to be certain of a complete division of the incudo-stapedial articulation ; or if the head of the stapes is seen lying free in the field it is certain that the incus has been displaced, and, by acting as a foreign body, may give rise to trouble if allowed to remain. If the long process is in view there is no difficulty in removing the ossicle.

In purulent cases it is still more important that the ossicle should be removed. Ludewig[58] found the incus carious in eighty-five per cent. of the cases upon which he operated ; in my own twenty-nine cases of purulent otitis, the ossicle was carious in nineteen, while in eight it had been completely destroyed. Prolonged manipulation in searching for the ossicle has not, in my hands, in any way added to the reaction following the procedure, nor has it interfered with the results. I should therefore earnestly advise prolonging the operation for the purpose of securing the incus rather than to perform a rapid operation and fail in its removal.

Among the complications which may interfere with the operation, hemorrhage is the one upon which especial emphasis is laid. Since I have operated with the patient in the semi-recumbent position, rather than with the head low, annoying hemorrhage has been the exception, rather than the rule. If it is sufficient in amount to interfere with the manipulation, it can always be checked by tamponing the canal firmly with cotton pledgets. It is important, in executing this manœuvre, that the first pledget of cotton should be carried well into the tympanic cavity, and also that the individual pledgets should not be too large, as upon withdrawing a large tampon, the force necessary for its removal is likely to lead to a recurrence of the hemorrhage. This objection is overcome if a number of small plugs are used instead of a few larger ones. It may be necessary to repeat the tamponing several times, but it will certainly effect its purpose if a little patience is exercised. A ten per cent. solution of cocaine is said to be useful in checking a slight oozing, but I have never had occasion to use it. Schmiegelow[59] has reported one case in which the hemorrhage following an attempt to excise the malleus was so severe that he was obliged to discontinue the attempt.

My own experience with intra-tympanic operations, more especially the particular class now under discussion, has led me to consider them remarkably free from risk. It is possible, however, for unpleasant sequelæ to

follow such procedures. Among these the most important are injury to the facial nerve, deafness due to impaction of the stapes into the oval window, injury to the labyrinth from accidental removal of the stapes, either by direct traumatism, or by infection, etc., and inflammation of the mastoid process.

The facial nerve is occasionally injured by the incus-hook. The cause of this accident is to be found either in a congenital defect in the Fallopian canal, or in the partial or complete destruction of its wall as the result of disease. With the exercise of a little care in manipulating the incus-hook, bearing in mind that great force is not necessary to displace the ossicle, the accident can usually be avoided. If the facial nerve is touched by the instrument, the twitching of the face immediately warns the operator of what has occurred, and subsequent caution will prevent serious injury. In one of my own cases, twitching of the face was noticed while attempting to locate the incus, and upon recovery from anæsthesia there was marked paresis of the corresponding side of the face; the facial nerve had been slightly involved before the operation, but after this the signs were much more pronounced. Daily faradization for about ten days was followed by complete recovery. Facial paralysis consecutive to a similar operation also occurred in a case reported by Ludewig.[60]

Complete loss of hearing following removal of the ossicles has occasionally occurred. In a case reported by Buck[61] the operator believed that the stapes had been impacted in the oval window during the operation. In one of Ludewig's[62] cases the stapes was accidentally removed and the hearing was entirely lost, while Wurdemann[63] reports a case of excision of the mallens in a patient about sixty years of age, in whom total deafness followed the procedure. The stapes was not interfered with in this case, and as there was persistent vomiting upon recovery from the anæsthetic, it is supposed that this led to a labyrinthine hemorrhage causing a complete loss of the power of audition. It seems manifestly unfair to record this as due to the operation, as the same accident might happen after anæsthesia for any other purpose. As far as accidental removal of the stapes is concerned, I cannot understand how it could have resulted in the total loss of the power of audition in Ludewig's case. The author expressly states that there was no evidence of purulent inflammation of the labyrinth from infection, and if this can be excluded, the only other event possible would have been direct injury of the labyrinth after the removal of the ossicle, which at the hand of so experienced an operator as Ludewig cannot be thought of. We know, furthermore, that the removal of the stapes alone is not followed by impairment of the hearing, even if considerable perilymph is lost. I am induced to class this case as one in which the result can hardly be attributed to the operation.

I have twice removed the stapes unintentionally: once, when there was ossification of the incudo-stapedial joint, the incus-hook removed the stapes, the incus being subsequently secured; in a second case, no force being used, the incus-hook, swept upward and forward, brought away the stapes, which upon examination proved to be necrotic. As no force was used here, I believe that the stapes had already been detached from the fenestra ovalis by long-continued suppuration. In both the above cases the hearing was not impaired, and in one it was improved.

With reference to severe mastoid inflammation as a sequel to the operation, Randall[64] reports a case in which this occurred; the observer remarks that the mastoid empyema may have been the result of an attack of influenza, which was almost epidemic at the time, but is inclined to believe that as the incus was not found during the operation it had been displaced toward the mastoid antrum, and by obstructing the escape of secretion gave rise to the mischief. That such accidents must occasionally happen no one can deny, but that they are very rare, so rare in fact that they can almost be looked upon as curiosities, is also true. This case also adds weight to the opinion already expressed as to the importance of removing the incus. Among my own cases there has not been a single instance in which unpleasant symptoms have followed the operation, with the single exception of giddiness, and this has been severe in five cases only.

My own operations of excision of the ossicles now number forty. In eleven cases the membrana tympani was intact, and of these two had previously suffered from purulent inflammation of the middle ear, ending in complete recovery. In ten instances the operation was done for the improvement of the hearing, being performed once for the relief of tinnitus, although the hearing was considerably impaired. In ten of these cases the mallens and incus were removed and all adhesions divided. In one case the incus was not found. Of this number great improvement followed in six cases, moderate improvement in four cases, while in the case in which the operation was performed for the relief of tinnitus, the hearing was not improved and the tinnitus was not relieved.

Of the cases much improved, in three a permanent perforation remained as the ultimate result of operation, although in two it was necessary to perform secondary operations under cocaine anæsthesia to secure this. In two the membrana tympani reformed completely, but the hearing remained so good that secondary removal was not required. In the remaining case the hearing was much improved so long as an opening remained in the membrana tympani, but returned to its original condition when this became obliterated. The patient passed from observation, as she resided in a distant city, and I have been informed that the physician in attendance has not been able to secure a permanent opening. In this case the incus could not be found, but the mastoid had been chiselled for an empyema one year before, and, as the ossicle was not seen during the operation, I am inclined to believe that it had been displaced during the treatment of the previous suppurative inflammation. In most of these cases an interval of many months has elapsed since the removal of the ossicles, and the improvement continues. It is only fair to say, however, that even when a permanent opening has been secured the hearing is not as good after the cavity has become completely dry, as immediately after the operation when the parts are moist. In those cases where the improvement continues, notwithstanding the complete reproduction of the membrana tympani, the hearing distance has remained as good as before the complete closure of the opening, and hence there has been no indication for further interference.

Of the cases slightly improved, in one the receptive apparatus was known to be involved before the operation, and only slight improvement was hoped for. In the second the stapes was anchylosed, and could not be mobilized (in a similar case I should now remove it completely); in the third, the operative treatment was resorted to at the request of a colleague, and the exact condition of the receptive apparatus was not known. In the fourth case, although the hearing was only slightly improved, tinnitus, which had been present, disappeared, and the hearing upon the opposite side became very much better. To this last fact I wish to call special attention, as it confirms the observations of Cholewa, already alluded to in considering tenotomy of the tensor tympani muscle. I have found this true in more than this one case, and on one occasion, after subjecting the opposite ear to operative treatment, this improvement disappeared. Since this time I have exercised great care in advising the employment of surgical measures upon the better ear, when this has improved after an operation upon its fellow. Whether the phenomenon is to be explained upon the theory advanced by Gellé,[65] to account for the modification of the hearing upon one side, when the air in the external meatus of the opposite side is compressed, or whether it depends upon the fact already proven by Edinger,[66] that the auditory nerve of one side receives fibres from the nucleus of the opposite side, I am not prepared to state. The influence which a pathological process in one ear exerts upon the functions of the other has long been recognized, and it is strange that more attention has not been given to this point, in the hope that one ear at least may remain useful as the result of

the early treatment of the affection upon the opposite side. The observations of Wharton-Jones,[67] Politzer,[68] Urbantschitsch[69] and others prove conclusively that this "crossed action" exists, and it certainly deserves more consideration than it has received. It carries with it the suggestion, however, that in cases where the conducting apparatus of both ears is affected, the receptive apparatus remaining intact or nearly so, surgical interference shall be first tried upon the poorer ear, and the effect be noted not only upon the ear operated upon, but also on the opposite side. From certain facts, I am inclined to believe that the rule is also applicable to cases in which the impairment upon the more affected side, or upon both sides, is the result of a chronic purulent otitis. Certainly I grow more and more cautious in advising operation upon the better ear, until considerable time has elapsed after the operation upon its fellow.

The above results, while not as gratifying as might be desired, still place the operation among the means which it is the duty of every otologist to advise when other measures fail. In this line Lucae[70] has probably operated upon more cases of chronic proliferative otitis media than any other single surgeon. It should be mentioned, however, that although he selected his cases with great care, and only operated when careful tests with the tuning-forks indicated a lesion of the conducting apparatus, he was content in the large majority of cases to leave the incus. As already stated, I believe that the removal of the incus is very important. Lucae reports 53 operations, with the following results: In 9 there was marked improvement; in 19 slight improvement; in 18 no improvement; while in 7 the hearing was impaired by the operation. Of the 9 cases in which the improvement was marked, the membrana was completely reproduced in 3, while a permanent opening remained in 14 of the cases in which there was only slight improvement. In these 53 operations the incus was removed in but 6 cases.

In cases where the membrana tympani has been partially destroyed, most of my own operations have been performed primarily for the relief of the purulent discharge, the hearing in a large number not being so seriously impaired that operative interference was sought for this cause alone. In cases of this character, then, our report must show the effect upon the suppurative process and also upon the function of the organ. When the operation is undertaken for the improvement of the hearing, an opinion as to the probable result should be based upon the result of an examination with the tuning-forks, according to the suggestions already given. It should be remembered, however, that the general results of operative procedures are better in such cases than when the inflammatory condition has been of the proliferative variety. Another fact which it is important to consider is, that when the hearing is good, surgical interference for the relief of purulency is not likely to impair the function of the organ. Thus in 29 cases of this character operated upon by the writer, in but one case has the hearing been impaired, and from a knowledge of the patient, and careful examinations, it is more than probable that this impairment is simulated.

Of these 29 operations, in 18 cases the hearing improved, and in 10 cases it remained the same as before operation. In but two of these last cases was the operation performed for the sole purpose of improving the hearing, and in one an unfavorable prognosis was given, and surgical treatment was resorted to only at the earnest solicitation of the patient. No improvement followed in this case, confirming in every way the opinion based upon the functional examination. On the contrary, in the other case the examination indicated that the removal of the obstructing conducting apparatus should improve the hearing. In this instance removal of the malleus, incus, and stapes, and the section of dense adhesions over the round window improved the bearing in the ear operated upon to such an extent that with the opposite ear tightly closed, conversation could be understood, this being impossible before the operation. The hearing in the opposite ear improved at the same time, but as other factors may have influenced this, it cannot be certainly credited to the operation upon the other side.

Of the 29 cases the discharge stopped completely in 15; it was greatly reduced in quantity in 9, while 5 cases are still under treatment.

In 14 cases the malleus and incus were removed, and in 4 the malleus, incus, and stapes. In 2 cases the ossicles had been completely destroyed by caries and the tympanic cavity was thoroughly curetted. In a single case the stapes alone was present, and as the head was carious this was removed, the foot-plate being left in position. In another case the malleus and incus were firmly adherent to the walls of the tympanum and could not be removed, but by the aid of the curette the carious areas were scraped away and the case was completely cured. In 7 cases the malleus alone was removed; in 5 of these the incus had undoubtedly been completely destroyed by caries; in 1 case it was overlooked during the operation, and subsequently found but not removed, while in the other case I may have displaced it into the mastoid antrum, as I felt certain of its presence early in the operation, but finally failed to secure it.

Ludewig[71] reports the results of removal of the malleus and incus in 75 cases, in 42 of which the discharge was cured as the result of the operative interference, while in 16 it continued after the operation. In 9 cases the patients were still under treatment at the time the report was written. In 5 cases no report was obtainable as to the result of the operation. Death occurred in 3 cases, but in no instance could it be traced to the operation.

Grunert,[72] in 28 cases operated upon, reports 13 cured. In 13 the discharge continued, and 2 cases were still under treatment at the time of writing. When it is remembered that the cases above reported represent those which have resisted all other means of treatment, there can be no question as to the advisability of undertaking the operation. The great danger is that the surgeon may mislead the patient as to the probable result of the procedure. It is seldom possible, in a given case, to assert positively that suppuration will cease completely after the operation. If the ossicles alone are carious, then their removal will put an end to the affection, but when the condition has existed for a long time it is quite possible that the adjacent tympanic walls have become involved, possibly in such remote situations as to be inaccessible to instruments. In such an event the procedure is advisable, but a complete cure cannot be promised. The indication for operation in such an instance lies in the fact that by the complete removal of the contents of the vault of the tympanum free drainage is afforded, and the danger of pus becoming confined in this space is reduced to a minimum. For this reason particularly, I insist upon the removal of the incus, as its presence interferes with drainage, and moreover it is the ossicle most frequently affected. Of the 75 cases of purulent otitis operated upon by Ludewig this ossicle was found carious in eighty-five per cent. Among my own cases I can remember no instance in which a healthy incus was removed. The probe sometimes enables us to determine the extent of the caries, but more frequently we are obliged to be satisfied with the simple fact of the presence of softened bone, without being able to define the extent of the area involved.

As to the question of impairment of the hearing when the procedure is adopted for the relief of suppuration, the hearing remaining fair, the results given above indicate that in very few instances has the hearing been rendered poorer by the operation. Out of Ludewig's 75 cases this occurred 6 times.

In view of the fact that all portions of the tympanic cavity are not accessible through the canal, and in order that the procedure may be more directly under the eye of the operator, Stacke[73] prefers to expose the parts by external incision. His method is as follows: An incision is made down to the bone, just behind the attachment of the auricle, and, following this in direction, from the tip of the mastoid process to a point just above the tragus. With a small elevator the cartilaginous meatus, and as much as possible of the periosteum of the osseous

canal are separated from the bony parts. In this manner the superior, posterior, and inferior aspects of the margin of the bony meatus are exposed, the soft parts being held only anteriorly. The soft parts are now divided transversely downward and forward, as deeply in the canal as possible, and by traction upon the auricle the funnel-like mass is pulled out of the bony meatus. The periosteum of the anterior wall is next divided, when the entire cartilaginous meatus and a part of the thin cutaneous lining of the osseous canal can, by traction forward, be so displaced as to leave the margin of the bony meatus entirely free. The tympanic structures can then be seen by direct light and all affected parts removed. By means of the gouge, the superior and posterior margins of the inner extremity of the bony meatus can now be removed, and the stapes being protected by a proper instrument, the curette can be freely used in the vault of the tympanum, the manipulations being under ocular inspection. In this manner the entire cavity can be completely cleared of necrotic tissue, and the mastoid antrum even may be exposed. In case there is evidence of serious mastoid involvement the original incision is made a little farther back than directed, and the antrum entered in the ordinary way, after which the tympanic cavity is exposed and treated in the manner above described, and finally the canal and the artificial opening into the antrum are thrown into one. In this way the middle ear, mastoid cells, and canal are converted into a single cavity, all parts of which are easily accessible through the external meatus.

After the operation the cartilaginous canal is replaced, and a drainage-tube, completely filling its lumen, is passed into the bony meatus, thus preventing displacement. The external incision is sutured, all drainage being through the meatus. In cases where the mastoid antrum has been freely exposed, it is usual to incise the soft parts of the canal longitudinally along the posterior aspect, and press the flaps thus formed backward into the cavity, holding them in position with tampons of iodoform gauze. In this manner a cutaneous lining for the mastoid antrum is secured. The same result is attained by cutting a quadrilateral flap from the cutaneous canal and carrying it into the antrum.

Stacke seems enthusiastic over this method of operation in cases of caries of the tympanum, but my own experience would lead me to employ it only in the most unpromising cases, and I should then be induced to first try the effect of excision of the ossicles in the ordinary manner. If there is mastoid involvement there can be no question as to the efficacy of the procedure. It should be borne in mind that the amount of space gained by exposure of the bony meatus is not as great as might be supposed, and unless the caries is extensive enough to make a thorough opening of the mastoid antrum desirable, a surgeon accustomed to operating through the canal will do quite as well by employing this method as the one above described.

Stapedectomy.—Accidental removal of the stapes has already been referred to as having occurred during the removal of the malleus and incus at the hands of different operators. Kessel [74] partially detached the foot-plate from the oval window in one of his cases. A quantity of perilymph was lost, but no serious consequences followed. Later, the experiments of Botey [75] proved that stapedectomy was not a serious operation, and might be beneficial in certain cases. It remained, however, for Jack [76] and Blake [77] to establish the removal of this ossicle as a distinct surgical procedure. The results reported by Dr. Jack are certainly very promising, and it is to be hoped that subsequent observations may demonstrate its utility beyond a shadow of a doubt. I have already given my own views upon the question of removal of the stapes alone, having clearly stated that they are not based upon any extended personal experience with the operation. On theoretical grounds, it seems that perhaps the removal of the entire ossicular chain might be preferable, but experience alone can determine this fact.

The procedure would be applicable to cases in which the hearing was impaired as the result either of non-suppurative inflammation, or of a suppurative inflammation which had been cured, leaving the stapes in an accessible position. If suppuration is present, then removal of all the ossicles would be the proper operation.

Steps of the Operation. (*a*) *When the membrana tympani is intact*, the incudo-stapedial articulation is exposed either by a curved incision in the postero-superior quadrant, close to the attachment of the membrane to the tympanic ring, or by a triangular incision in this situation, or by the incisions already described in the operation of exploratory myringotomy. After the incudo-stapedial articulation is brought into view the stapedius muscle should be completely divided; the incudo-stapedial articulation is then severed, and the long arm of the incus pushed forward so as not to interfere with the subsequent steps. If the presence of the incus still interferes with the separation of the stapes the long process may be seized with the forceps, and the ossicle removed. The stapes is then freed from adhesions binding it to the oval niche by means of the sharp straight knife, and is removed by gentle traction with the forceps, or by a hook passed between the crura. It is important to sever the stapedius muscle completely before disarticulation, as otherwise, after disarticulation, the stapes may be pulled out of view. If the foot-plate is found anchylosed, this condition may be treated in the manner already suggested; although in such a case, as the parts would be subjected to more violence, it is probable that removal of the malleus, incus, and membrana tympani would diminish the chances of reaction after the operation.

Blake [78] has advocated the performance of this operation under cocaine anæsthesia, a ten per cent. solution being first introduced into the tympanum, through the catheter. After the first incision through the membrana tympani, the direct application of the cocaine solution to the middle ear, by means of a cotton-tipped probe, renders the subsequent steps painless. In three cases of this kind I have been able to clear the oval niche in the above manner, no pain being experienced after the first incision. I am inclined to think that the introduction of cocaine through the Eustachian tube has very little effect in mitigating the pain of the first incision, and if a very sharp knife is used this is never severe. After this no pain need be felt if the cocaine is carefully applied. My results have been very satisfactory, but I am inclined, at present, to employ this method more as an exploratory than as a therapeutic procedure, for the purpose of determining how much improvement can be hoped for by any operation upon the conducting mechanism. When, for any reason, general anæsthesia is objected to—unless great improvement can be assured,—the measure above detailed is of great value in deciding this point; but under general anæsthesia, much more exact work can be done if the membrana and two larger ossicles are first removed.

After the removal of the stapes the flap is replaced and the meatus is occluded by a plug of antiseptic cotton, which is left in position for several days unless inflammatory symptoms supervene. The wound usually heals in a few days, and in no case has the reaction been severe.

(*b*) *When the membrane is partially destroyed*, the stapes or the incudo-stapedial articulation may be already in view; but if they be not visible, the appropriate incision for the exposure of these parts will vary in each case, after which the technique given above is to be carried out. In two cases operated upon under local anæsthesia, the stapes being clearly in view, extraction was easily accomplished and the results were flattering, in one instance the hearing for a low whisper increasing from seven to thirty feet; here the entire stapes was removed intact. In the second case only a portion of the ossicle was secured, yet the improvement was considerable. It is well to bear in mind that even slight hemorrhage will render the removal of the stapes difficult, and when this region is covered by dense structures which bleed freely when incised, it may be necessary to remove the malleus and incus and remains of the membrane to secure a suitable field for the performance of stapedectomy.

The after-treatment may be the same as in the preceding class of cases. It is well, however, to inspect the

ear at the end of twenty-four hours, and if signs of inflammation are present, to cleanse it frequently with a mild antiseptic solution. If, however, the parts are perfectly dry, they should not be disturbed, for fear of interfering with the healing process.

Edward Bradford Dench.

EASTBOURNE. One of the most popular seaside resorts in England. It is situated on the Sussex coast, between Brighton and Hastings. Eastbourne is only sixty-five miles from London. Dr. Yeo ("Climate and Health Resorts") speaks as follows concerning the merits of this place:

"The roads and streets have been skilfully planned and laid out on a uniform system, so as to secure abundance of space, free ventilation, and the picturesque planting of trees throughout the streets of the town. Moreover, the streets and other residential parts of the town are not all huddled together close to the shore as in some resorts, but spread out over a considerable tract of land extending toward the magnificent downs behind the town, for three-quarters of a mile or more from the sea-shore. This is a great advantage, for it enables the physician to make use of Eastbourne for many patients who are not comfortable when close to the sea, and for others to whom the exciting effect of strong sea-air might prove injurious, while the pure, bracing air of the downs, which are so readily accessible from the inland part of the town, might be advantageous.

"The sanitary arrangements are as complete as they can well be made, and an abundant supply of pure, soft water is obtained from wells sunk through chalk into the green sandstone. Every house has a constant supply. The sewers are freely ventilated, and the sewage flows into the sea at a point three miles away to the east, where the tides carry it away without the chance of its returning to the bay. The death-rate is low, the annual average for the last three years being 14.18 per 1,000."

The same author also states that during the summer he has known phthisical patients to do extremely well at Eastbourne, especially if they begin their stay by living away from the sea. Cases of torpid scrofula, of slow convalescence from surgical operations or injuries, cases of anæmia and general want of tone, cases of depressed function, nervous or digestive, are all suited to this place. In houses built to the west of the town, and with rising ground between them and the east, the winter temperature is not unpleasantly low, and there is more than the average amount of sunshine. But those parts of the town which are unprotected from the east suffer much from the prevailing winds in spring.

The country surrounding Eastbourne is attractive, and the place undoubtedly deserves the growing favor with which it is regarded in England. The accommodation offered in numerous hotels and lodging-houses is fairly satisfactory. *Edmund C. Wendt.*

ELECTRO-THERAPEUTICS. The advances in electro-therapeutics since the first issue of this work have been important. In no department, perhaps, has there been more activity than in the relation of electricity to the diseases of women. The most extravagant statements have been made by extreme partisans as to the extraordinary efficacy of the new methods in dissipating fibroid tumors, and in curing almost every variety of uterine disorder. There is a large class, however, who are extremely pessimistic in their views as to the therapeutic properties of electricity, and who deny that it possesses any considerable value in gynecology.

When, however, a man possessed of the experience of Keith, of Edinburgh, can say that many are prejudiced against electricity because they consider it quackery and know nothing about it, that his confidence in its power to relieve disturbing symptoms of uterine fibroids and to cure many chronic inflammatory conditions of the pelvis continues to increase, and that he has no fear for the future of electricity, we have testimony that must greatly outweigh assertions and opinions that are purely negative.

In a recent and animated discussion of the subject at the Société de Chirurgie of Paris, equally favorable opinions were advocated by the majority of those engaged in the debate; and the strength of these opinions was accentuated by the fact that the majority of those who hold them are signally distinguished as laparotomists.

A word in regard to the faradic current in its relation to diseases of the uterus. Its effects are mainly mechanical, and according to the construction of the helix and the length and thickness of the wire do we measure its action on the muscular tissues of the uterus. Applied directly to the uterus of animals in physiological experiments, the organ visibly contracts, although not to

such an extent as the intestines, which, on application of the electrodes, can be seen to draw up gradually, very much after the manner of a woman's work-bag. Its action on the smooth muscular fibres of the human uterus, when applied therapeutically, is analogous to that of ergot, although manifestly more prompt and energetic, especially under the influence of the positive pole, which possesses a much greater power over the involuntary muscles than the negative. It is a current of alternation, of constant closing and breaking; hence it produces a sort of interstitial massage, heightening the activity of the circulation, accelerating absorptive processes, and influencing favorably the nutrition of parts.

Faradization, by its power over muscular contractions, sensibly increases temperature. According to the chemistry of the development of heat during muscular contractions, muscular work is the result of the decomposition of nitrogenous substances, and the muscles grow at the same time that they work and develop heat. That the value of the faradic current is more limited than the galvanic in the treatment of uterine disease must be immediately manifest to all who appreciate the difference between them; but in some conditions which come within the range of its physical and physiological activities, the faradic current may exceed in efficiency the galvanic. By its direct excitation of the smooth muscular fibres of the uterus we are enabled to combat that stasis of the circulation which is the beginning of uterine inflammation.

By this method we obtain a veritable interstitial massage, that is potent in overcoming the primary inertia of the organ and in preventing an arrest of retrograde metamorphosis, through which comes sub-involution with its inevitable and persistent sequelæ. In its purely local influence, then, faradization would seem to be preventive rather than curative, so far as it relates to uterine disease; or rather it is preventive, so far as concerns the latter conditions of uterine engorgement, and curative only in its initial stage. When the processes that go to make up the graver and more chronic diseases of the uterine parenchyma and its lining membrane have continued a long time, as is usually the case when medical interference is sought, the simple mechanical effects of the faradic current would be altogether misdirected.

Here we resort to the electrolytic influence of the galvanic current, or rather to what may be more fitly termed its galvano-chemical cauterizing effects through which are destroyed the granulations and fungoid growths of the diseased mucous membrane. By the interpolar influence of the current we correct a languid nutrition and hasten the absorption of exudations.

Just as the positive pole of the faradic current has an action of its own, superior in effect to the negative in causing uterine contractions, so the positive pole of the galvanic current has an action peculiar to itself. Here oxygen is generated and acids accumulate which render this pole directly hæmostatic. It is, therefore, indicated in all hemorrhagic conditions, as well as where there exists an excess of the natural secretions. Owing, also, to the greater retractibility of cicatrices following positive galvano-cauterization, the results are more lasting in the treatment of fungoid growths, or vegetations, than could possibly be the case with the negative pole.

At the negative pole, on the contrary, the alkalies precipitate, imparting caustic properties and causing effects fluidifying rather than hæmostatic. The absorptive process is undoubtedly more active under this pole than under the positive, and is especially indicated in indurated chronic metritis and for the resolution of fibroids.
